When no shadow-outline is discernible, the illumination of the entire pupil fading gradually into darkness whatever may be the direction in which the mirror is rotated, the eye is myopic in such degree that its far-point lies at the distance of the eye of the observer—case V.

b. Distinctness of the shadow-outline. The definition of the shadow-outline is always less perfect than that of the image of the flame at the fundus of the observed eye, for the reason that the (virtual or real) image of this image, which we may regard as the object actually viewed by the observer, is formed either at an infinite distance from the pupil of the observed eye (in emmetropia), at a finite and always considerable distance behind the pupil (in hypermetropia), or at a finite and always considerable distance in front of the pupil (in myopia). In no case, therefore, can this image be perfectly focussed by the eye of the observer, when, in accordance with the requirements of the test, the latter is accommodated for the pupil of the observed eye. Nevertheless, in high grades both of hypermetropia and of myopia, the difference in the distance (from the observer) of the pupil and the image is not so great as to prevent a fairly distinct view of both at the same time. In hypermetropia (case II.) of decreasing grade, passing through emmetropia (Case I.) and myopia of relatively low grade (Case III.), to the limiting grade of myopia (Case V.), in which the image of the visible circle at the fundus of the observed eye lies at and fills the pupil of the eye of the observer; likewise in myopia of relatively high grade (Case IV.), decreasing to approach the same limit (Case V.), the distinctness of the shadow-outline diminishes at a rapidly increasing rate, until, in the limiting case (Case V.), the shadow-outline and the shadow-movement vanish together.

Again, the image of the flame at the fundus of the observed eye is itself imperfectly defined, except in the particular case in which the far-point of the observed eye lies exactly at the distance of the (virtual or real) image of the flame as formed by the mirror. When the test is made with a plane mirror—see Fig. 576—this particular case implies myopia of low grade, which, as already stated, is a condition unfavorable for obtaining a distinct view of the image of the flame at the fundus of the observed eye. When, on the other hand, the test is made with a concave mirror, the higher grades of myopia offer the most favorable conditions both for the sharp definition of the image of the flame at the fundus and for seeing the outlines of the real image of this image, consequently for good definition of the shadow-outline.

Narrowness of the pupil, whether of the observed eye or of the eye of the observer, is favorable to the definition both of the image of the flame, at the fundus of the former, and of the image of this image, as pictured on the retina of the latter. But narrowness of either pupil, and still more of both pupils, involves a notable limitation of the area of the visible circle—see Fig. 575—and narrowness of the pupil of the observed eye involves also a diminution (in the ratio of the square of its diameter) of the brightness of the image of the flame at its fundus. Furthermore, a narrow pupil is unfavorable for observing the passage of the shadow. For these reasons, it will readily be comprehended that the preponderance of advantage may be greatly on the side of a large and well-lighted pupil, and this is in practice found to be the case. To this end the diameter of the hole in the mirror should be somewhat greater than that of the pupil of the observer's eye, and the pupil of the observed eye, unless naturally rather wide, should be dilated by instilling a solution of one of the weaker-acting mydriatics.

c. Brightness of the pupil. We have given the name "visible circle" to the circular area, at the fundus, from which alone any ray of light can both pass out of the observed eye and enter the eye of the observer. Under the conditions of the shadow-test the visible circle is simply that portion of a larger illuminated area (image of the flame) which, seen always in circles of confusion, is visible through the pupil of the observed eye. The image formed on the retina of the observer's eye is, therefore, an indistinct image of the visible circle, but by reason of its indistinctness, together with the fact that its outline is the same as that of the pupil of the observed eye, the impression made on the observer is rather that of an illuminated pupil than of the portion of the fundus behind it. As the size of the image on the observer's retina is independent of the actual size of the visible circle it follows that the larger the visible circle (its brightness being assumed to be constant), or the brighter the image of the flame (the size of the visible circle being assumed to be constant), the stronger will be the illumination of the pupil.

The area of the visible circle is larger, (α) the wider the pupil of the observed eye, (β) the wider the pupil of the observer's eye, (γ) the greater the myopia of the observed eye in excess of the critical grade (case V.), in

which the far-point of the eye lies at the distance of the pupil of the observer's eye, (δ) the less the refraction of the observed eye measured from the same critical grade of myopia, and (ε) the less the distance of the observer's from the observed eye.

The brightness of the image of the flame at the fundus of the observed eye is greater (α) the wider the pupil of the observed eye; and, when the test is made with the concave mirror, the greater the apparent area of the mirror, that is, (ε) the less the distance of the observer's eye (looking through the hole in the mirror) from the observed eye, or (ζ) the larger the concave mirror.

The conditions favorable to a strong illumination of the pupil of the observed eye are then, (α) wideness of its pupil, (β) a fairly large pupil on the part of the observer, (γ) a high grade of myopia of the observed eye, (δ) a high grade of hypermetropia of the observed eye, (ε) a short-observing distance, and (ζ) the use of a large concave mirror. Of these conditions, the first (α) may be secured when necessary by resorting to artificial mydriasis; the second (β) is best attained by observing with relaxed accommodation, the observer correcting the far-point of his own eye for the distance of the pupil of the observed eye by means of a suitable lens mounted behind the hole in the mirror. A short observing distance (ε) may be tried whenever the condition of the observed eye (*e.g.*, exceptionally dark pigmentation of the fundus, narrowness of the pupil from extensive synechiæ; imperfect transparency of the media, etc.) is unfavorable to good illumination of its pupil. The use of a concave mirror of large diameter (ζ) is also a possible resource in cases of exceptional difficulty.

d. The rapidity of the shadow-movement (other things being equal) varies inversely with the diameter of the visible circle, over which the image of the flame passes as the mirror is rotated; the smaller the visible circle, the less will be the time occupied in this passage, consequently the more rapid will be the movement of the shadow across the pupil. The darkening of the pupil occurs most quickly in myopia of the particular grade in which the far-point of the observed eye lies at the distance of the pupil of the observer's eye—Case V.; the passage of the "shadow" is progressively slower in higher grades of myopia, also in lower grades of myopia passing through emmetropia and the lower and medium grades of hypermetropia to hypermetropia of high grade.

e. The form of the "shadow" is determined by the form of the image of the source of light. If this is approximately circular the shadow-outline will be correspondingly curvilinear, and the shadow will have the form of a crescent. When an Argand burner is used the shadow-outline appears as a somewhat ill-defined straight line—see Fig. 577.

When the shadow-test is made with the concave mirror, the direction of the shadow-movement is in every case the opposite of that observed when the plane mirror is used. But with this exception there is no essential change in the reactions. When the observer is stationed at a fixed distance, of say one metre, the concave mirror has the advantage of affording a stronger illumination; when the test is made at a shorter and varying distance, the plane mirror is to be preferred.

The complete theory of the shadow-test as applied to the investigation of astigmatism is too complicated to be adequately presented in an elementary paper.

The shadow-test is, on the whole, the most exact method which we possess for the objective determination of the refraction of the eye. As compared with the determination of the refraction with the ophthalmoscope by the direct method, it is both more accurate and easier of execution; and this is especially true in the higher grades of myopia, in which measurements made with the ophthalmoscope are always very unsatisfactory. In the measurement of astigmatism it has an advantage over the ophthalmometer of Javal-Schiötz, in that it reveals the total astigmatism of the eye and not merely the corneal asymmetry. On the other hand, the shadow-test affords almost no information regarding the condition of the fundus of the eye under examination, and none as regards its acuteness of vision. The true value of the shadow-test is therefore as supplementing, not as superseding, other methods of examination.

The technique of the shadow-test is comparatively easy to acquire, and it calls for almost no special apparatus; an ophthalmoscope furnished with a concave and a plane mirror and a Rekoss disk, or a clip for holding a correcting glass, and a short tape-measure graduated to fractional parts ($\frac{1}{4}$, $\frac{1}{3}$, $\frac{1}{2}$, etc.) of a metre make up the list of essentials. *Carl Koller.*

SINUSES RESULTING FROM ABDOMINAL SECTION.—These are sequelæ in abdominal surgery which are by no means uncommon, and unfortunately they have failed in very many cases to receive such efficient treatment as would be desirable. In other words, an efficient technique for this form of injury has not yet been devised. Of course, the persistent sinus after injury to, or operation upon, deep-lying tissues, has been recognized ever since men have observed the phenomena which follow injuries, ever since surgery has been practised as an art which is far from infallible. The sinuses following bone injuries, glandular abscesses, etc., are lesions which are in some cases but too familiar. But the sinuses which attend abdominal surgery are, of course, a matter of recent observation, because abdominal surgery itself is but a development of yesterday. Furthermore, it is only since the development of pelvic surgery that these lesions have become comparatively frequent—which means that the number of operators is far greater now than formerly, as is also the number of cases to be operated upon; and I suspect the average ability of the operators is not as great as in the days when abdominal surgery was rarely attempted except by men of mature experience and keen powers of observation. On the other hand, all who operate now have the benefit of the accumulated experience of three-quarters of a century of abdominal surgery, and the wonderful advantages which have accrued from the antiseptic theory.

A sinus may be regarded in all cases as an illustration of a perverted or a perverse inflammatory process, an accumulation of wasted energy, a prodigal effusion of vital force, and a sinus of the abdomen is no exception to this statement. It is at once an evidence of the prodigality of nature in the expenditure of her resources, and of her conservatism in her constant attempts to repair injuries, the *vis medicatrix naturæ*. An extreme illustration which will serve as a type is the following case, which was seen in the autumn of 1891.

The patient was a young Irish woman about twenty years of age, who had been operated upon, several months prior to the time when I saw her, for tubercular peritonitis, the abdominal wound having been left open for drainage. The peritoneum had secreted freely, but instead of agglutination of the visceral and parietal surfaces, the parietal surfaces remained free, while a wall of new tissue gradually formed over the omentum and intestines, completely isolating them from the parietal peritoneum. This wall or sheath had its upper limit several inches above the umbilicus, extended well into the flanks laterally, and apparently had its lower limit at the brim of the pelvis, though the bladder and uterus were wholly outside of it in the great sinus between the layer of new tissue and the abdominal wall. This latter circumstance may have been due to the fact that the drainage-tube dipped into the pelvic cavity behind the uterus. The new membrane was not very vascular, dark brown in color, and friable. It showed no tendency to adhere to the parietal peritoneum, secreted more or less abundantly, and apparently showed little tendency to contract. In fact, this was an example on a colossal scale of a persistent sinus resulting from abdominal section. The wonderful power of the peritoneum as a secreting organ is shown in such processes. Instead of a sinus, it frequently throws out bands and adhesions in various portions of the abdominal and pelvic cavities. It suggests the cuttle-fish throwing out ink, obscuring the water, and then swimming away from its pursuers. That is, this seems like an effort at conservatism on the part of nature, though it

may prove deleterious, perhaps destructive. The exudate which is thrown out becomes organized with connective tissue and blood-vessels like other tissues which are the result of an inflammatory process, but the organization is a low one, and though it may contract, it may not contract enough to obliterate the newly formed channel, if a channel has been newly formed, and though retrograde metamorphosis may be established, the process may not be vigorous enough to dispose of the viscera which have suffered from its attachment. So there may be a persistent and annoying opening in the belly with a discharge of pus, or of gas and fæces if the intestine has been perforated, a constant dribbling of urine if the corroding process penetrates the bladder. The consequences are discomfort and disgust to the patient, possibly pain and prolonged invalidism, and a tax upon the ability and ingenuity of the surgeon which he may be unable to fully satisfy.

The causes of the condition in question may be considered as constitutional, irritative, and septic.

1. Predisposing may be a better term than constitutional. Cases in which the peritoneum, from any cause whatsoever, has contracted a habit, as it were, of throwing out excessive secretion are by virtue of that habit favorable cases for the formation of sinuses after abdominal section. This is notably true in connection with tuberculosis of the peritoneum, although it is also true that the effect of opening the peritoneal cavity in such cases is frequently curative, and that if sinuses are formed the necessary and desirable retrogressive changes occur with greater relative frequency than in non-tuberculous cases. Predisposition to sinus formation is also present in connection with syphilis, malignant disease of the peritoneum, or disease of any of the abdominal viscera in which the visceral or peritoneal circulation is seriously interfered with. In cases in which an abundance of adhesions, either recent or ancient, is found in the abdominal or pelvic cavity, as the result of an inflammatory process, we are in the presence of an irritable peritoneum, with a predisposition to sinus formation under favoring conditions. The mere agglutination of coils of intestine to each other may be the first step in this process, and should these become adherent to the parietal peritoneum in the vicinity of the abdominal wound, and the latter fail to close, or be reopened by a force from above or below, the sinus would be complete.

2. The cause which seems more fruitful than all others in the production of sinuses, I have termed irritative. Perhaps it would be better to speak at first of mechanical irritation, for septic causes are also irritative, but act chemically as well as mechanically. Drainage and suture or ligature material, of whatever substance composed, is the principal means by which this irritative action is caused. At present I am considering only its irritative action as a foreign body, without reference to the septic elements which are frequently associated with it. Chief among these irritative agents are glass drainage-tubes. It matters little whether their calibre be large or small, when used too long in some cases, and when used at all in others, whether properly or improperly adjusted, the result will be a sinus. Their presence is an irritant to the sensitive peritoneum of the intestines and omentum, which snugly embrace them. The exuding secretion in a short time (Tait says in seventy to eighty hours) forms a mould around the tube, the intestines are agglutinated to the mould and to each other, and thus a cavity is formed which is walled off from the abdominal viscera. When the drainage-tube is removed the concentric pressure of the surrounding structures upon the walls of the sinus may cause them to collapse, and disintegration and absorption may gradually accomplish their complete removal. But in the unfavorable cases these results do not ensue, but the sinus walls become more completely organized and the consequent phenomena of granulation may continue indefinitely. Sinuses may also be caused by the irritation of too many or too large sutures or ligatures around tissues which have shrunk or atrophied. Such an irritation may be an aseptic one, as has been shown by Bumm. Such sinuses are without the well-marked wall which occurs when a drainage-tube has been the irritating cause. They are formed by the agglutination of coils of intestine, the exudate varying in thickness, of course, with the intensity of the process and the sensitiveness of the peritoneum to irritation. The track of such sinuses may be long, irregular, and intricate, and they may contain pockets of considerable capacity, which will give rise to no end of uncertainty and surmising in attempts at exploration and treatment. That ligatures are the cause of sinuses was long since observed by the earlier ovariotomists, and this fact induced some of them to endeavor to dispense with them as far as possible, especially the large ligatures which are required for pedicles. Thus Keith substituted the actual cautery for the pedicle ligature, and Peaslee devised a method for cutting and removing the pedicle ligature after it had been adjusted long enough to insure freedom from hæmorrhage. These methods have never been improved upon, though they have been forgotten or ignored by many abdominal surgeons. The use of gauze as a means of drainage within the abdomen is a step in the direction of progress. The irritation which it causes is probably less intense than results from the use of any solid material. The gradual withdrawal of the gauze is probably more favorable to the breaking up of newly formed plastic material than the withdrawal of the drainage-tube, and the entrance and development of poisonous germs within the peritoneal cavity is certainly as little facilitated by this as by the use of any drainage material which has as yet been suggested. These and other considerations have induced some surgeons to discard the drainage-tube in favor of gauze, especially in view of the fact that drainage with gauze seems to be quite efficient. The matter is of so much importance that it is worthy of more extensive study and discussion than it has yet received. The same objections which have been urged against glass drainage-tubes are applicable to tubes of rubber, bone, or other more or less firm material. It is assumed that the subject of drainage of the abdominal cavity is intrinsically so important that it will be universally admitted that substances should be used which will be certain to provoke the least possible irritation.

3. The subject of sepsis as a cause of abdominal sinuses is as yet too obscure to admit of careful and exact statements. Sinuses not infrequently occur when no drainage-tube has been used. The abdominal wound may have been carefully sealed, but sinuses have resulted. It has already been stated that ligatures, by their very presence as foreign bodies, excite more or less irritation, but in how many instances there are also foci of irritation in the form of blood, pus, or serum, within the abdomen or pelvis, or poisonous material which has been introduced from without, which the peritoneum cannot or does not absorb or successfully isolate. The gonococcus may be instanced as a form of infection from without, though Bumm affirms that the gonococcus alone will not cause septic peritonitis, that it is infectious only upon mucous membranes, and that its injurious effects cease after it has traversed the mucous membrane of the Fallopian tube ; also that when it reaches the peritoneum it becomes harmless, and is encapsulated. Possibly Bumm is correct in his statement that cases of septic peritonitis in which the gonococcus is found are illustrations of mixed infection, the streptococcus which is often associated with the gonococcus being the efficient cause of the peritoneal injury. However this may be, the investigations and observations with reference to the question immediately at issue have been mainly clinical. I have found no record of autopsies bearing upon the question, and as Sänger has observed (*Deutsche med. Wochen.*, xvii., 1891, p. 145), experiments like those of Heinricius, Loebker, and Delbet upon cadavera and animals furnish no convincing argument. We are still very much in the dark as to the rôle which is played by micro-organisms in the matter. The results which attend the formation of abdominal sinuses are bad enough. The condition is that of a granulating wound which is both annoying to the patient and destructive of

vital force, like persistently granulating processes in any situation. There is more or less interference with the functioual activity of the intestines and danger to vital organs such as results in all cases from prolonged suppuration.

Consequences with which all are familiar in such cases, are fistulæ of the intestines and bladder, prolonged vesical irritation and cystitis, inflammatory diseases of the kidneys, anæmia, and intensification of pre-existing tubercular or syphilitic processes. Whatever benefit may have been derived from the performance of the original operation, and the removal of diseased structures, is neutralized by the morbid condition which has been engrafted, and a very important problem is furnished for consideration, for which no satisfactory means of treatment has as yet been devised. Treatment is rendered the more difficult by reason of the fact that it is frequently impossible to explore the cavities with sufficient thoroughness, on account of their sinuosities, on account of the large areas which are frequently involved, and on account of the danger of wounding the intestines or the peritoneum, if active measures of treatment are adopted. The alternatives with which one is confronted in the matter of treatment are simple expectancy, palliative measures, or radical ones—that is, the reopening of the peritoneal cavity, extensive and difficult dissection, and possible inability, even after such efforts, to treat the condition successfully. Expectant treatment means doing nothing, throwing the responsibility of the situation upon the natural reparative forces. This may be the method of laziness, or of despair, but it is astonishing how frequently nature is equal to the emergency, if suitable measures are adopted for maintaining the general nutrition. With a fair degree of vitality of the tissues and functions a spontaneous cure not infrequently results, and it is not improbable that many cases which pass from the surgeon's observation, and are no longer heard of, are cured in this way. But there are many others which remain uncured, the patients suffering varying degrees of annoyance, but not sufficient to compel re-entrance into a hospital and submission to radical procedures.

The palliative method of treatment offers a choice of many measures, the degree of success varying with the vitality of the patient, the area of the sinus, and the adaptability of the measures to the given condition. A prerequisite to success is cleanliness, which means not only cleanliness of the surface of the body contiguous to the opening of the sinus, but cleanliness of the walls of the sinus, its secretions being removed with sufficient frequency and thoroughness. This may not be easily accomplished, and a freqnent cause of persistent sinuses is the retention and decomposition of secretions. Irrigation should be practised at least once a day with hot Thiersch solution, hot solution of carbolic acid, creolin, or any other suitable astringent. It is unnecessary to say that the abdominal opening should be kept sufficiently large for the ready exit of discharges. Applications of strong solution of nitrate of silver will sometimes sufficiently stimulate the sluggish granulation process. Trypsin will corrode and digest the new tissue, but it is very dangerous, unless used with sufficient circumspection. In one case, in which it was recommended by me, it produced an opening into the bladder, and in another into the intestine. The former was cured by persistent drainage of the bladder, the latter by resection of the intestine. In a number of cases I have seen good resnlts from packing the sinus with iodoform gauze; in sinuses which are extensive in area, I have seen it fail. Tbrough drainage into the vagina may be efficient, and it may result in failure, as I have experienced. A pedicle ligature may be the cause of a sinus, but the sinus may not heal even after the ligature has been extruded. For obstinate cases, there remains only radical treatment, that is, reopening the abdomen, breaking up adhesions, and dissecting away all adventitious tissue. This may be an operation of great magnitude, and I have known it to fail even with the most skilled operators. It seems to me, however, that it is the true method for the treatment of obstinate cases, and I doubt not that increased experience in technique will make it successful, even in such cases. In all cases it must be remembered that violence in exploration, in injection, or in irrigation, are to be rigorously avoided. We must not forget that we are in intimate contact with the thin and often friable wall of the intestine, and that too much manipulation will almost inevitably resnlt in a more serious condition than that from which the patient is already suffering.

Andrew F. Currier.

SIRADAN. A small spa, in the Department of Hautes-Pyrénées, Fraunce.

Location.—Siradan is a little village, long noted for its calcareo-sulphated and chalybeate springs. It is devoid of scenic attractiveness, being situated in an arid valley, about twelve miles from Bagnères-de-Luchon.

Access.—By way of Bordeaux and Solichan on the South of France Railroad.

Analysis.—According to Filhol, one thousand grammes of the principal spring contain:

	Grammes.
Bicarbonate of lime	0.2000
Bicarbonate of magnesia	0.0255
Sulphate of lime	1.3600
Sulphate of magnesia	0.2800
Sulphate of soda	0.1090
Chloride of calcium	0.0500
	2.0255
Carbonic acid, free	18 c.c.

Traces of chloride of potassium, sodium, calcium, magnesium, oxide of iron, silica, iodine, phosphate of lime, and organic matter.

The chalybeate springs are cold, and supply a water of moderate ferruginous strength and average composition.

Indications.—The waters of this spa are employed in gastralgia, abdominal plethora, gravel, and vesical catarrh, as well as chlorosis and anæmia.

Accommodation.—The thermal establishment is modern and satisfactory, but the boarding-houses are of an inferior order.

E. C. Wendt.

SKULL, FRACTURES OF THE BASE OF. As in fractures of other portions of the skull, the fracture itself is of comparatively minor importance, and the extreme gravity of these injuries lies in the injury to the base of the brain which is very certain to accompany them. In order to fnlly understand the subject it is essential to consider some peculiarities of the base of the skull and its relation to the portions of brain overlying it.

If we view the skull as a whole from either side, and especially from the rear, it will be noticed that while the upper and posterior surfaces have a dome-like arch, the shape of which is well calculated to resist any ordinary violence, the base or under surface, especially viewed from the rear, is nearly flat. This is more strikingly apparent if we make a transverse and vertical section just back of the foramen magnum. This will show that the base of the skull at that point is almost exactly flat, and lacks the arched contonr calculated to withstand blows or pressure. This will be made evident by reference to the accompanying illnstration (Fig. 578) of a transverse vertical section just back of the foramen magnum.

A glance at the under surface from without will show that it is weakened, not only by the large foramen magnum, but by the numerous foramina on either side and in front of it. If the base be viewed from within, being held between the observer and a moderately strong light, a considerable portion of the entire base will be found to be quite translucent, and some portions almost transparent, owing to their extreme thinness. The posterior fossa of a skull before me is thinner than at any other portion of its entire contour. In this specimen it is easy to distinguish through the posterior fossa small objects held on the other side of it, the bone here being as thin as the thinnest paper.

While it would appear that the thicker portions of the

base, as, for instance, the condyles on either side of the foramen magnum, the mastoid portions of the temporal, the median portion of the sphenoid, and the elevated ridges on the occipital bone, add considerable strength, in reality they do not furnish as much addi-

tional support as would at first appear; for if we make sections of these above-mentioned thicker portions, we shall find that they have only an extremely thin layer of outer and inner table or solid bone, and that almost their entire thickness is made up of diploë. They do not nearly compensate for the extreme thinness of the greater portions of all the fossæ and for the numerous foramina. It will therefore appear evident that the base

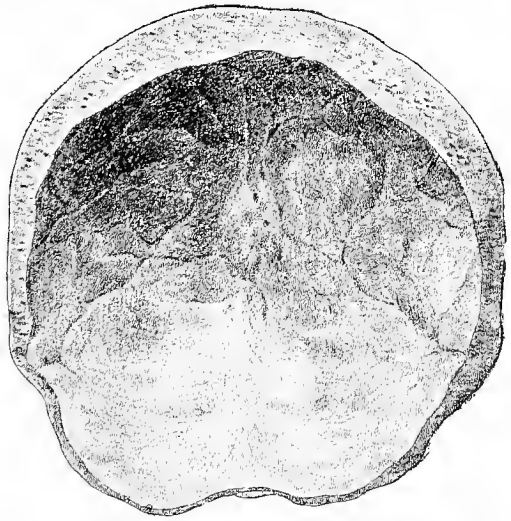

FIG. 579.—Transverse Vertical Section of the Skull, Three-quarters of an Inch Posterior to Foramen Magnum, contrasting the thinness, flatness, and consequent weakness of the base with the thickness, convexity, and strength of the vertex. (Author's Specimen.)

of the skull is relatively weak, and not calculated to withstand more than a moderate amount of violence. The greater portion of the base has little or no diploë. No diploë is to be found in the posterior fossa and in the orbital plates of the frontal bone.

If it were not that the base of the skull, from its less exposed position and from its being to a great extent protected from direct violence by being enclosed by the structures of the neck beneath, and by the fact that its great mobility upon the cervical vertebræ lessens the danger from any direct violence, it would be much more frequently fractured.

Viewed from within, the contour of the entire base is remarkably irregular, containing many ridges, angles, and sharp edges of bone which might, therefore, when fractured, cause severe injury to the portions of brain overlying them.

In this respect, however, we are liable to some misconception in examining skulls from which all the soft parts have been removed, for during life these sharp angles and ridges are somewhat rounded off and protected by being overlaid by dura mater and by the large venous sinuses and other blood-vessels.

The under surface of the brain, that contiguous to the base of the skull, is of greater importance, and any in-

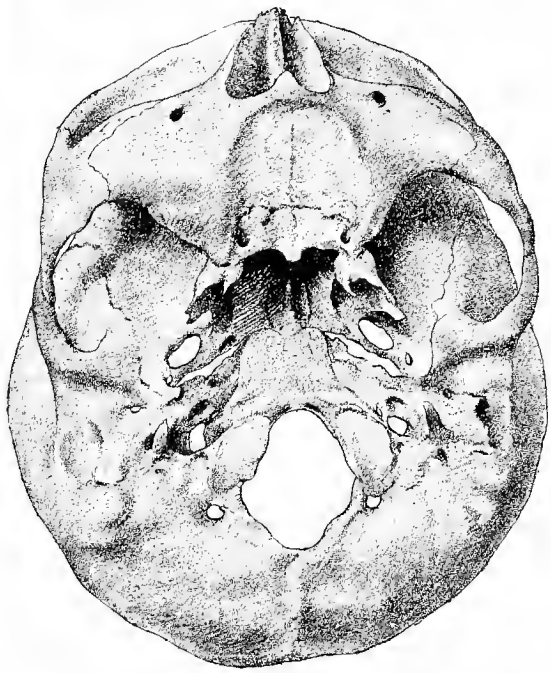

FIG. 580.—View of Base of the Skull, showing as far as possible to what extent it is weakened by foramina. (Author's specimen.)

juries of it much more serious than those of its upper surface, and it is principally for this reason that fractures of the base are more disastrous than those of the vertex.

Hilton has drawn attention to the extremely important manner in which the cerebro-spinal fluid protects the base of the brain from injury. He has shown that almost the only part of the base of the brain which is in close apposition with the base of the skull is the inferior portion of the anterior lobes of the cerebrum, where they rest upon the orbital plates of the frontal bone, and that all the other portions of the base of the brain, including those parts most essential to life, do not rest upon the bones at all, nor even touch them, but that under these portions of the brain there is such an abundant accumulation of cerebro-spinal fluid that it forms what he aptly terms a water-bed. No other portions of the brain are thus protected by an abundant supply of cerebro-spinal fluid to break the force of any violence. The contour of the two posterior lobes of the brain does not, therefore, correspond to that of the portions of the skull over which they float on this water-bed.

CAUSES.—Fractures of the base of the skull may result either from direct or from indirect violence. Cases

are recorded in which the orbital plates and the ethmoid or sphenoid bones have been perforated by slate pencils, scissors, canes, swords, pieces of stick, tobacco pipes, bayonets, umbrellas, and points of foils used in fencing, thrust through the orbit, nose, or mouth, and in one instance by a fall against a meat hook.

The most remarkable case which I have been able to find recorded is described in the *American Journal of the Medical Sciences* for July, 1850, by Dr. Bigelow. A solid bar of iron, three feet seven inches long and one and one-fourth inch in diameter, was driven by a premature explosion of a blast, entirely through the skull of a man twenty-five years of age, high into the air, and fell several rods distant. The bar passed upward beneath the zygomatic process on the left side, and through the floor of the anterior fossa of the base of the skull, and emerged near the centre of the frontal bone close to the coronal suture. A considerable portion of brain-substance was

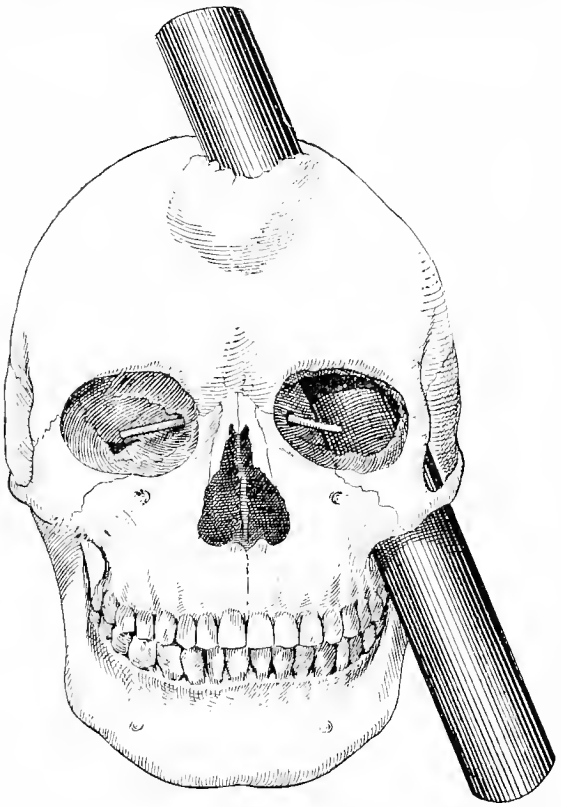

FIG. 581.—Case Reported by Dr. Bigelow, of an Iron Bar (43 inches long and 1¼ inch in diameter) driven upward through the skull. Recovery.

lost. The patient was almost immediately able to converse rationally, and rode three-quarters of a mile, sitting erect in an ox-cart, and after alighting from the cart without aid, walked up a long flight of stairs. His recovery was complete in all respects, excepting the loss of sight in the left eye.

Perforations have also occurred in various parts of the base of the skull from gunshot wounds. Wounds from direct violence of this kind are much more common in the anterior fossa than in other portions of the base, its floor being so thin that but little force would be required to thrust any of the above-mentioned foreign bodies through into the brain. Punctured wounds through the anterior portion of the orbit by small slender instruments or weapons, leave but very little external evidence of injury. If slender weapons be introduced under the upper lid, nothing is visible but a slight amount of ecchymosis of the conjunctiva. If the wound be external to the lid there will be nothing visible but the small wound in the region of the eyelid or eyebrow; and as the brain symptoms from such a wound of the anterior portion of the brain may not appear for several days, the gravity of the case or the nature of the injury may be entirely overlooked.

Nancrede has called attention to the fact that murderous wounds leaving no trace that can be detected, except

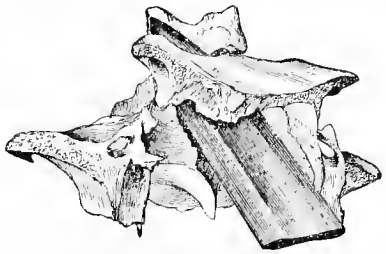

FIG. 582.—Fracture of Clinoid Process by Sword Thrust. (From Surgical History of War of Rebellion.)

upon a very careful examination, could be readily effected by passing a small pointed instrument through the retro-tarsal conjunctival fold, and then penetrating the delicate orbital roof and superjacent brain. While this would not be difficult in an adult, it would be especially easy in children.

The ethmoid bone has been fractured by a blow upon the nose driving it upward against the brain.

The squamous portion of the temporal bone has been fractured by a blow upon the chin driving the condyle of the lower maxilla through the glenoid fossa.

It is easy to appreciate how, if a man fall from any considerable height, and especially if, falling upon his head, he strikes upon any soft surface, thus distributing the force of the blow over a considerable area of the vertex, the weight of the body being projected like a blow from a hammer, with the momentum gained by a descent of many feet, against the base of the skull, an extensive fracture of the base would easily be produced. These fractures should be considered as caused by direct violence. As the entire weight of the individual's body, projected from a height of a number of feet, constitutes the fracturing force, it would seem very easy for extensive fissure of the base to occur.

The base may also be fractured by an individual falling a considerable distance and alighting upon the knees, pelvis, or feet, the skull being driven so forcibly against the cervical vertebræ as to produce fracture of the base.

The above-mentioned fractures, although considered by some as illustrations of contre-coup, are the result of direct violence by impact of the base of the skull against

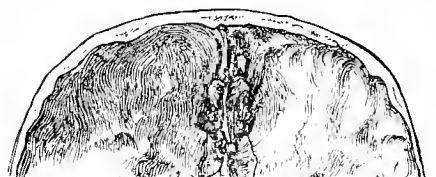

FIG. 583.—Fracture of Anterior Fossa from a Blow on the Nose. (Bryant.)

the cervical spine, and not properly from contre-coup, as formerly considered by Chopart and others, who have recorded their cases of contre-coup. Counter-stroke, as a factor in the production of fractures of the base, probably very rarely occurs, and is much less often referred to in modern medical literature. A fracture by contre-coup is one in which the fracture is produced on the side of the head opposite to that on which the blow is received. Grima's definition of contre-coup is: "A lesion produced

by a blow in another place than that which received the blow." The fracture is caused by the violence being transmitted through and around the skull. In a considerable proportion of cases the fracture at the base is a result of the extension of a fissure from a fractured vertex. In those cases in which there is fracture of both vertex and base, the direction of the fracture is from the vertex toward the base. The theory of Aran, who made numerous experimental investigations, was that fractures of the base are always connected with fractures of the vault from which they radiate, following a line within the zone in which the former occurred, and taking a course which corresponds with the shortest route to the base. Aran based his theory upon numerous experiments with dead bodies, and upon old dried skulls.

Fractures of the base are generally, if not in all cases, only fissured and without marked depression, as in fractures of the vertex.

Symptoms.—The symptoms are often obscure, and the diagnosis may not be made out with certainty at the outset. Symptoms usually appear early, but may be long delayed, and all may be absent until three or four hours before death, as in a case recorded by Jackson. Hilton mentions an interesting case of a gentleman who was

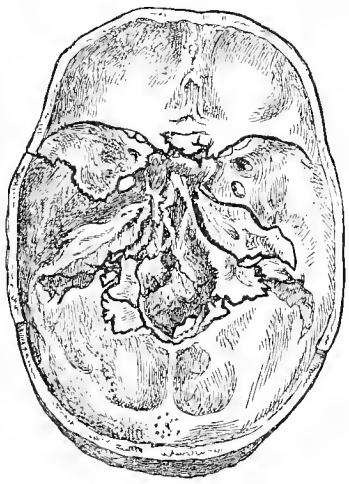

Fig. 584.—Fracture of the Base by a Fall on the Vertex, which was fissured. (Erichsen.)

thrown from his horse, striking upon the back of the head, and he was dragged by his foot catching in the stirrup. He subsequently disentangled his foot, mounted his horse again, and rode several miles home. He occupied himself about his usual duties for the following thirteen days, driving, walking, and attending to various business matters, previous to coming under Hilton's care. He then began to suffer from indications of paralysis and subsequently died, and an examination of his skull showed that he had suffered a fracture at the base. Yet during the thirteen days following the injury, there was not the slightest evidence of any brain lesion.

Owing to the location of a fracture of the base, and to the fact that such fractures are only fissured and with little or no depression, it is not possible to make out by inspection or palpation the lines of fracture, as can be done in those of the vertex. The manner in which the violence has been inflicted would guide us very much in our diagnosis, and the symptoms will depend upon the portion of the base which is fractured.

Hæmorrhage from the ears alone is of only moderate importance, for it may occur without fracture, simply from any laceration of the small vessels of the external auditory meatus, or the membrana tympani; but if the hæmorrhage be prolonged and copious, and especially if it be evidently arterial, as shown by pulsation, and if it be accompanied by other symptoms, or the nature of the accident be such as would be likely to produce fracture of the base, it is a symptom of considerable importance, but is not alone quite conclusive. Severe hæmorrhage from the ear has occurred without fracture of the base. This symptom does not occur even in all fractures of the middle fossa, but only when a fracture through the petrous portion of the temporal bone establishes a communication between the injured intra-cranial vessels and the cavity of the tympanum, the membrana tympani being also ruptured. If, in such cases, the membrana tympani was not ruptured, the blood would escape through the Eustachian tube into the throat.

Serous discharge from the ear is the most important and almost characteristic symptom of fracture of the base. This discharge is sometimes very copious, so much so that it is recorded that as much as a tumblerful has been discharged in a short time. It has been pretty conclusively proven that this consists of cerebro-spinal fluid, for its composition, whenever examined, has proved to be the same, and there would appear to be no other possible source for such a copious discharge of fluid corresponding in chemical composition. It was at one time erroneously supposed that it was the serum of the blood, or the fluid secreted by the internal ear. The cerebro-spinal fluid is a perfectly clear fluid of a very pale yellow color, and having a specific gravity of about 1.010. It has a saltish taste and its reaction is alkaline. It contains a substance which, according to Foster, although not sugar, acts like dextrose when tested with Fehling's solution. Five cases have been recorded by Wilder (*Medical News*, Philadelphia, 1885, vol. xlvi., pp. 625–627), in which brain-substance escaped through one ear. Of these, three were fatal and two recovered. The discharge of cerebro-spinal fluid is only possible when there has been a fracture of the petrous portion of the temporal bone, with rupture of the dura mater and arachnoid, and of the membrana tympani. Cerebro-spinal fluid has rarely been discharged through the nose, when the line of fracture extends through the anterior fossa. In a case recorded by Cameron in *The Lancet*, London, 1884, vol. i., p. 205, there was copious discharge of cerebro-spinal fluid through the nostril and one ear; but the patient, although seventy-five years of age, recovered. Erichsen reports a case (fatal) of a boy who received a wound on the back of the head, with depressed and comminuted fracture of the skull, through the wound in whose scalp a large quantity of cerebro-spinal fluid escaped. This discharge of serous fluid by itself is a very characteristic symptom, and when taken in connection with an accident the nature of which would be likely to produce fracture of the skull, would constitute almost positive proof. A very noteworthy case has, however, been reported by Page (London *Lancet*, 1888, vol. i., p. 774) of a sailor who, after a fall of twenty feet, had ptosis of right eye, partial loss of vision in left eye, and hæmorrhage from left ear and nose, followed by copious, clear serous discharge from left ear, and insensibility. Nearly complete recovery soon followed, but he died seven weeks after the accident, and at the autopsy no fracture could be found, but only purulent meningitis. Paralysis of one or several cranial nerves has occurred as a result of fracture of the base. Hæmorrhage from the nose and mouth, and subsequent vomiting of blood, may arise in many cases where there is no fracture. But if the hæmorrhage be considerable, and if the nature of the accident were such as was likely to cause a fracture of the base, it may be supposed that the source of the hæmorrhage is probably from rupture of an intra-cranial vessel, the blood escaping from a fracture of the sphenoid or ethmoid bones forming the roof of the nasal fossa. Vomiting of blood in considerable quantity, without hæmorrhage from nose and mouth, has occurred from fracture of the base, the blood having been previously swallowed. I have at present under my care a boy ten years of age, who seven days ago fell fifteen or twenty feet upon a bare wood floor, striking upon the right side of the occipital bone. Vomiting of blood continued frequently for at least twenty-four hours. There was slight hæmorrhage from the right nostril and right ear, followed by serous discharge from the right ear. He is improving.

Hæmorrhage into the orbit may occur to a very noticeable extent when a fracture implicates the orbital plates, the blood then escaping from the intra-cranial vessels into the areolar tissue of the orbit, and appearing very noticeably under the ocular or palpebral conjunctiva. The discoloration of the lids from such a cause would not usually make its appearance as promptly after the injury, nor be accompanied by as much swelling, as when due to contusions of the lids from direct violence.

Loss of vision from hæmorrhage into the orbit may occur, as recorded by Rohrbach.

The only objective evidence of hæmorrhage from fracture of the base may be the appearance, after a number of hours, of extravasated blood beneath the skin on the back or side of the neck. In such cases the blood flowing from the broken skull finds its way down along the cellular-tissue until it appears beneath the skin, in the neck. Such extravasations beneath the skin are of considerable diagnostic importance, if there has been no direct violence at the location of such extravasations to account for them.

Vertigo, deafness, otorrhœa, hemiplegia, impairment of vision, and priapism have also been recorded as symptoms. There is no one symptom constantly present in all fractures of the base.

Prognosis.—Fractures at the base are not as invariably fatal as was formerly supposed. There can be no doubt that recovery occasionally occurs. The prognosis as to the injury of this portion of the skull itself, if there were no accompanying lesion of the brain, would not differ from fractures of other portions, for repair may take place here as in other portions of the cranium. If the patient survived long, union would probably take place, although slowly. According to Hewett, in some cases, even after months and years, no trace of union of the fragments could be found. In others the line of fracture was found partly united by dense fibrous tissue and partly by a thin layer of inlaid bone, while in others bony union was perfect. In some instances of bony union there was an excessive formation of porous bone, it being heaped up along the line of fracture. Usually, however, the injury to the brain results fatally. It is hardly possible for an amount of violence sufficient to produce fracture of the base to fail to produce concussion, laceration, or compression of this, the most delicate part of the brain. As in fractures of other portions of the skull, the prognosis depends almost entirely upon the amount of injury to the brain. Bryant, however, reports a series of thirty cases, with twelve recoveries. In these twelve the injury to the brain consisted of simple concussion.

Charles Phelps has collected a series of seventy cases of fracture of the base with twenty-one recoveries, or thirty per cent.

J. A. Lidell has called attention to the fact that the prognosis is more favorable in fractures caused by the impact of gunshot projectiles, and has collected from the Medical and Surgical History of the War of the Rebellion, one hundred and thirty-five examples of more or less complete recovery from such injuries. Of these cases thirty-five recovered sufficiently to go back to duty permanently or enter the Veteran Reserve Corps, or be mustered out of service without pension. He shows that in many of the cases of recovery the disability from cerebral lesions subsequently increased with lapse of time. Thus apparent recovery may not be permanent. He ascribes these results to the fact that in such compound fractures extravasated blood and inflammatory products can readily escape from within the skull through the wound, and thus cerebral compression be avoided. It would be fair to consider that the same would be true to some extent of punctured wounds by canes and swords, etc., provided no portion of the foreign body remained within the skull. Lidell states that in about half of the one hundred and thirty-five cases the fracture occurred in the anterior fossa, and, therefore, infers that such injuries of the anterior fossa and anterior lobes are less fatal than those of other portions of the cerebral base.

Even though recovery may appear to take place, it may not be permanent, for there is danger of development of epilepsy or paralysis, or death from secondary brain disease subsequently. The prognosis would be especially unfavorable if, in cases of any direct violence by sticks, canes, gunshot, or other foreign bodies, any portion of the missile remained unextracted.

Recovery may occur in patients of almost all ages. Rouse records the recovery of a boy aged seven. In a series of twenty-two cases of all ages (twelve fatal), four of the patients who recovered were boys under ten years of age. (St. George's Hospital Reports, London, 1879, vol. x., pp. 125–128.) Even very prolonged coma does not render the case hopeless. W. J. Barkas reports the recovery of a girl, seven years old, under very adverse hygienic conditions, after twenty-one days' partial or complete unconsciousness. Parsons reports the recovery of a man, aged forty-eight, after being twelve days in a semi-comatose condition.

Recovery may be incomplete, and there may remain or be subsequently developed otorrhœa, headache, loss of hearing or taste or smell, unsteadiness of gait, local paralysis, and mental impairment, or epilepsy.

Treatment.—In those fractures caused by canes, swords, and other missiles penetrating the skull, the indications would be to remove the foreign body as completely and quickly as possible, and if the point of injury be accessible to the trephine, that instrument would furnish better access for the removal of foreign bodies than would any operation by cutting forceps. Aside from the removal of foreign bodies where possible, and the employment of strict antisepsis to the wound, little can be done. In all other fractures of the base, it is impossible generally to detect any depression of fragments, or to remove or elevate them where there is such displacement, and therefore the treatment would resolve itself into the simple measures for antisepsis and for insuring perfect quiet to the patient, and such measures as would be resorted to for the prevention and relief of the intra-cranial inflammation which would result from fractures of other portions of the skull. An ice-cap should be applied, and due attention given to the condition of the patient's bladder, and bowels, and diet. The head should be kept as immovable as possible, and in some severe cases it would be advantageous to secure immobility by a plaster cast.

It would rarely happen that in fractures of the base any operation would be indicated.

In all punctured fractures of the base caused by weapons or missiles, and in all other fractures in which the lines of fracture open communication with the air, as through the nasal passages or ear, and thus render the fracture compound, thorough antiseptic measures should be employed. If the nasal passages be involved, these should be frequently and thoroughly subjected to the spray of a solution of peroxide of hydrogen, and occasionally irrigated with a solution of the same from a Thudicum nasal douche apparatus. It would seem barely possible that if solutions of bichloride of mercury were used, absorption might take place to an injurious extent, considering the great extent of the nasal mucous membrane; or that some of the solution might be swallowed by the patient. The anterior nares should be plugged with sublimated gauze after each irrigation or use of spray. It would be difficult or impossible to keep aseptic any compound fracture communicating with the nasal passages.

If the communication be through the ear, this should be thoroughly cleansed and its interior irrigated with peroxide of hydrogen, and all the surrounding surfaces made clean by shaving off the hair and washing with ethereal or other soap, and made thoroughly aseptic with solution of carbolic acid, four per cent., or bichloride of mercury, 1 to 1,000. A dressing of sublimated gauze should then be applied.

It should be remembered that in syringing solutions into the ear in these cases, it may not be impossible to inject the fluid within the skull against the brain, through the same route by which the cerebro-spinal fluid escaped; and this would indicate that our antiseptic liquids

should not be strong enough nor of a kind to act as irritants.

Roswell Park (*Medical News*, December 1, 1888) has demonstrated the efficiency of boric-acid solution, 1 to 100, as a germicide; and it would therefore (as endorsed by Keen) be a very good substitute for the hydrogen peroxide.

In compound fractures of the posterior portion of the occipital bone, the scalp should be shaved and thoroughly cleansed, and antiseptic dressings be applied, and depressed fragments be elevated when accessible. In every case of possible fracture of the base, it is of extreme importance to insist that the patient be kept absolutely quiet, and on no account be allowed to get up for a considerable length of time, even though he feel quite able to do so. Hilton calls attention to the great fatality which results from failure to rigidly restrain the patient in a recumbent position, even though he feels perfectly well, for a prolonged period. *Thomas H. Russell.*

SNOW-BLINDNESS (Ger., *Schneeblindheit;* Sw., *Snöblindhet*). Hunters and trappers in the Arctic regions, as well as mountain climbers in southern latitudes, often suffer from an affection of the eyes, to which, from its supposed causation by the glare of the sunlight reflected from the snow, the term snow-blindness has been applied. It is encountered occasionally during the winter season in the northern and western parts of this country, but is a common complaint only in the far north, and there only during the spring or summer, when the sun is well above the horizon. It follows very closely, in its degree of greatest prevalence, the isothermal lines in the three continents bordering upon the north pole, being observed much further south in America than in the continents of the eastern hemisphere.

The affection begins usually with a feeling of irritation of the conjunctiva, as if there were fine sand in the eye, and there is usually also a slight cloudiness of vision, objects appearing to the observer as if seen through a mist. This is followed by sharp burning pain in the eyeball, extending thence around the orbit into the temple. Photophobia and lachrymation are usually marked, and blepharospasm, independent of the photophobia, is not uncommon. The sight becomes at times markedly impaired, and this failure of vision may come on so suddenly and be so pronounced, that the sufferer cannot distinguish the landmarks, and, if alone, may be unable to find his way back to camp.

Examination of the eye at an early stage shows merely a slight hyperæmia of the conjunctiva, with moderate contraction of the pupil. When the condition is further advanced we find increased hyperæmia and chemosis of the conjunctiva, the latter being usually confined to that portion of the cornea which is exposed to the direct rays of light when the eye is open. In the more severe cases cloudiness, or even ulceration of the cornea has been observed. Examination of the fundus of the eye reveals, as a rule, nothing beyond a slight redness of the optic nerve.

There are two theories concerning the production of snow-blindness. The older one is that the affection is the result of a molecular change in the retina, caused by over-stimulation by the glare of the sun shining through an atmosphere containing but little moisture, and reflected from the glistening snow. This retinal affection causes pain and photophobia, and excites reflexly an irritation and inflammation of the conjunctiva. The main objections which have been urged against this theory are, first, that there are no changes in the retina, visible upon ophthalmoscopic examination, sufficient to account for the symptoms, and, secondly, that recovery of vision and relief of the discomfort follow very rapidly when the eyes are protected from the action of direct sunlight.

The second, and more plausible theory is one recently advocated by Dr. A. Berlin ("Om Snöblindhet," *Nordiskt Medicinskt Arkiv*, No. 3, 1888). This writer, who studied the affection during an Arctic expedition which he made with Nordenskjold's party, regards it as primarily an erythema of the conjunctiva due to the direct action of the ultra-violet chemical rays of the sun upon this membrane. It occurs, he says, in regions characterized by an intensely cold atmosphere and low humidity. As it is the particles of moisture in the atmosphere that absorb the sun's rays, the latter ought to exert a more intense action here than they do in lower latitudes, where the humidity is relatively much greater. And this, in fact, is the case, for Arctic travellers and mountain climbers speak frequently of the burning heat of the sun even when the temperature of the atmosphere is very low, and it is well known that the unprotected portions of the skin are more affected by the action of the sun in the far north and at great elevations than in other regions, a painful dermatitis being the result of even short exposure. Dr. Berlin believes that snow-blindness, or conjunctivitis erythematosa, as he prefers to call it, and dermatitis from sunburn are due to the one and the same cause, viz., the direct action of the sun's rays, and that the process in the two affections is the same, consisting of first hyperæmia and then exudation and the formation of blebs, attended by an intense burning sensation. He compares this to the other condition, also called snow-blindness, which is caused by the irritation from fine particles of snow blowing against the eyes during a blizzard. The latter is manifestly a traumatic conjunctivitis, but the symptoms are nearly identical with those of the first form. Another fact which the author cites in support of his view is that often only one eye is affected, and that the one exposed to the sun. For example, he observed that when the members of Nordenskjold's Greenland exploring party were marching westward, they suffered from snow-blindness confined to the left eye, but that the right eye was the one attacked when they were walking in the opposite direction. Dr. Rosendale, who agrees with Berlin as to the nature and cause of the affection, also reports several cases occurring in hunters, in whom snow-blindness began in the eye most exposed to the direct rays of the sun ("Fall af Snöblindhet," *Hygeia*, 1891, p. 299).

Among the older writers, who looked upon the affection as one due to retinal changes, strychnine was a favorite remedy. Soothing applications were also made to the eyes, and the patient was kept in a dark room until all signs of irritation had subsided. It is claimed, however, by recent authorities, that the affection will subside readily in a few days if the patient avoid the direct sunlight. It is not even necessary for him to be confined to a dark room.

As a prophylactic measure Berlin recommends the wearing of goggles made of a moderately fine wire network, without glass, fitting closely around the eyes. The

Esquimaux use "snow-eyes," which are simply goggles made out of a thin disk of wood having a minute transverse slit. A mode of protection frequently employed by trappers and hunters in the far North is the smearing of the nose, cheeks, and eyelids with a gunpowder or other dark paste. It is a curious fact that this manner of protecting the eyes from the glare of the sun is in use over very widely separated parts of the globe, and is by no means confined to the inhabitants of the polar regions. In *Nature*, vol. xxxiii., 1885, Mr. Ralph Abercromby writes that nose and face blackening is in use by the natives of Morocco as a preventive against the effects of sand glare, by the Fijians to shield themselves from the water glare, and by the inhabitants of Likkim to prevent the effects of snow glare. The efficacy of this measure as a preventive of dermatitis from the action of the sun and of snow-blindness also serves to strengthen Dr. Berlin's view that the latter is nothing more than a sunburn of the conjunctiva. *Thomas Lathrop Stedman.*

SODIUM DITHIOSALICYLATE. This is the sodium salt of an acid formed by the reaction that occurs when salicylic acid and sulphur chloride are mixed together in molecular proportions at a temperature of 120° to 150° C; the decomposition of the sulphur supplying the elements for the formation of dithionic or hyposulphuric acid, which combines with the salicylic acid. A large isomeric series is possible, but only two are utilized, the sodium salts of which are known as sodium dithiosalicylate I., and sodium dithiosalicylate II. The acids themselves are not employed for any therapeutic purposes, the sodium salts only being used. No. I. has not been used to any extent except in veterinary practice, in which two and a half and five per cent. solutions are used in the treatment of foot-and-mouth disease. No. II. is the salt usually employed. It is a grayish-white powder, very hygroscopic and entirely soluble in water. On the addition of acids a precipitate of yellow viscid drops is formed consisting of dithiosalicylic acid.

This salt is a powerful antiseptic, and is said to be superior to the salicylates in the treatment of acute and gonorrhœal rheumatism. It is given in doses of three grains, twice a day in mild cases, and more frequently when the attack is severe. It may be repeated as frequently as every hour. It is said to cause the pain, fever, and swelling to disappear in from two to six days. It has the advantage of a smaller dose and freedom from disagreeable effects. It does not irritate the gastric mucous membrane, nor cause nausea, tinnitus, or any sense of depression and collapse.

Locally it is used as an antiseptic lotion, its germicidal action being much more marked than that of salicylic acid. A twenty per cent. solution is said to destroy the spores of the anthrax bacillus within forty-five minutes.
Beaumont Small.

SODIUM TETRABORATE. Introduced for the purpose of replacing boric acid on account of its greater solubility and more active antiseptic properties. The kolyseptic or development-arresting action of boric acid on bacterial life is very marked, but being soluble only to the extent of four per cent. in water, its action is not very certain, especially where the solution may be diluted by the secretions and discharges. Tetraborate of soda is soluble to the extent of sixteen per cent., and forms a much more active antiseptic solution.

It is formed by heating together equal parts of boric acid, borax, and water; when the solution cools the compound separates as neutral crystals. It is recommended for use whenever boric acid is indicated, and is perfectly unirritating, harmless, and stable. *Beaumont Small.*

SOLUTOL AND SALVEOL. Are two patented disinfectant fluids, their active ingredient being cresol. These solutions differ from other cresol solutions, as creoline and lysol, by being free from the objectionable property of soapiness which is characteristic of these excellent disinfectants. In solutol the cresol is rendered soluble by the action of sodium cresylate. It is said to contain in every three and a half ounces, two ounces of cresol, one-fourth free and three-fourths combined as sodium cresylate. Salveol holds the active ingredient in solution by the aid of sodium cresolate in the place of sodium cresylate.

Both solutions possess all the disinfectant properties of cresol, but the former being an alkaline and caustic solution, is not applicable to ordinary work. It is very suitable for all household purposes, as it effectually disinfects closets, sinks, infected bed clothing, utensils, etc. It is very soluble in water, and may be diluted as desired. Salveol is a neutral solution, and may be used for all medical and surgical purposes for which a disinfecting fluid is required. A one-half per cent. solution is used for surgical dressings and for ordinary surgical work. It is not at all irritant, and is said to be more active than a two per cent. carbolic-acid solution. It is perfectly soluble in water, forming a clear solution.
Beaumont Small.

SOMNAL. (Ethyl-chloral-urethane.) Introduced as an hypnotic by Radlauer, of Berlin, in 1889. He described it as a true chemical compound formed by the direct combination of chloral alcoholate with urethane. By some it is said to be simply chloral-urethane or ural under another name.

It is properly a clear, colorless crystalline powder, with a hot burning taste, and very deliquescent, but is supplied in the form of a liquid on account of its instability. It is an alcoholic solution, one part in three.

It is used solely as an hypnotic, the dose being from twenty to thirty minims for adults. It resembles chloral in the rapidity of its action, but there is no depression produced. No unfavorable after-effects follow its employment, the appetite remains good, and its action on the pulse, respiration, and temperature is negative. In a great number of cases it produced sleep within fifteen minutes to an hour, and the sleep lasted from three to six hours to the whole night. The sleep is not profound. The action of the drug is sedative, and it has proved most satisfactory in the insomnia and restlessness of chronic diseases, and in convalescence from acute diseases. In delirium tremens it is not very certain in its action, nor has it proved satisfactory in acute inflammatory diseases.
Beaumont Small.

SOZOIODOL. (Di-iodo-para-phenol-sulphonic acid.) An acid base which was introduced in 1887 as an antiseptic. It contains forty-two per cent. of iodine, twenty per cent. of carbolic acid, and seven per cent. of sulphur. It is prepared by treating dio-iodo-benzol with fuming sulphuric acid and adding sulphuretted hydrogen. It is also said to be formed by adding two parts of crude carbolic acid to one part of strong sulphuric acid; the reaction raises the temperature for about two days, and when this has subsided, any excess of carbolic acid is removed and iodine added. The acid itself is not employed, but it forms salts which possess all the properties of the acid. The potassium and sodium salts are the ones most employed. They resemble one another in physical characters, forming in colorless, well-defined prisms, soluble in water, the potassium compound in fifty parts, and the sodium in fourteen. The sodium salt is the more efficacious of the two. A two per cent. solution entirely prevents the development of pus cocci.

The use of these compounds is in all those conditions in which iodoform is likely to be proved useful. It is said to be preferable, as it is soluble in water and glycerine, does not decompose when exposed, readily combines with other substances, and is free from irritating action and disagreeable odor. The salts are used as a dusting powder, either pure or mixed with French chalk, or lycopodium powder, or in the form of an ointment of the strength of two per cent. It is particularly serviceable in parasitic skin diseases. A one or two per cent. solution is used to irrigate the bladder when antisepsis is wished for, and as a wash in ozæna and other purulent catarrhal discharges. The zinc salt has been specially recommended for gonorrhœal discharges. In acute forms a half to one per cent.

aqueous solution is used with two and a half per cent. of laudanum added. In chronic forms salicylate of bismuth is added in the place of the laudanum. It is best used when the inflammatory action is beginning to decline, it then rapidly checks the secretion and hastens a cure. The zinc salt is also used in all conditions in which the sodium and potassium salts are employed. It is soluble, one part in twenty of water. All the solutions should be freshly prepared and not exposed to the light, as they are decomposed and free iodine liberated.

The mercurial salt is a lemon-yellow powder, soluble in about five hundred parts of water. It is mainly employed in the treatment of syphilitic affections. A powder or ointment of twenty per cent. strength is employed for ulcerations of the surface in disease of the nasal and other cavities. A wash when used should not exceed five per cent. It has been recommended as the most suitable form of mercury for hypodermic injections. The injections should be made in the gluteal regions, alternately on the right and left side. It causes a little pain, but the local effects are said to be much less than with any other mercurial salt. The dose is one and a half grain, and one injection a week is equal to three of other forms of mercury. The absorption of the drug is rapid, and the gums have to be carefully watched, as its action is very marked. *Beaumont Small.*

SOZOL. Is the name applied to the paraphenol-sulphonate of aluminium, one of the latest antiseptics. It occurs in crystalline granules of a strong astringent taste and faint carbolic odor. It is very soluble in water, glycerine, and alcohol, and forms very stable solutions.

It is not a powerful antiseptic or bacteriacide, but has been found to be a very serviceable application to wounds, ulcers, etc., as it possesses an astringent action in addition to its antiseptic properties. In cystitis it has been used to irrigate in a one per cent. solution. Not much is yet known of the therapeutic properties of this drug, and its value cannot now be estimated. *Beaumont Small.*

SPARTEINE. Is the alkaloid obtained from broom, *Cytisus scoparius*. It is a volatile oily liquid, very unstable, allied to coniine in appearance, chemical composition, and action. It is only used in the form of the sulphate of sparteine, which occurs in colorless, odorless, transparent needles, very soluble in water and alcohol.

Sparteine was introduced as a tonic for the heart, and proposed as a substitute for digitalis in the treatment of heart diseases and dropsy, by Laborde and Germain Sée. Although it has been employed for a number of years, it has not proved to be of very much service, nor can its action be said to be thoroughly understood. Although very contradictory reports concerning its action have been furnished, it is now very generally recognized as being much weaker than digitalis, but more rapid in producing its effect. It appears to be indicated in the cases in which there is lack of compensation without any organic lesion, and in the early stages of valvular disease. In cases of long-standing disease it is not of any benefit. Another class of cases in which it is indicated are those in which a rapid action is required and where delay would be dangerous. It is thought to have a cumulative action. On the heart it acts as a tonic to the muscular tissue, rendering the beat more slow and powerful, and correcting any irregularity in its action. This is followed by diuresis, due to the effect on the kidneys and blood-pressure. The dose is from one-half to one-third grain repeated three or four times a day; this may be increased to much larger quantities, as much as three or four grains daily. It may be given as a pill or in solution, and has also been used hypodermically.

The sulphate of sparteine is also reported (*Therap. Gaz.*, June, 1892), to have been used with marked success in the treatment of various forms of tremors. A number of cases are reported, in all of which rapid relief was obtained by taking one-fourth to one-half grain doses three times a day. The patients were both young and aged, and the tremors were due to the effect of paralytic strokes, syphilitic disease, and other causes. This effect is probably explained by its action on the motor nerves, which it depresses from the periphery to the centre, and to its tonic action on the heart and system generally. Its action, other than on the heart, has not been studied to any extent. *Beaumont Small.*

SPINAL CORD, SURGERY OF. I. SPINA BIFIDA.—In Volume VIII. of the REFERENCE HANDBOOK OF THE MEDICAL SCIENCES, p. 471, is an excellent account of Spina Bifida, by Dr. Robert W. Lovett. The only point necessary to be discussed here is the question of treatment. In the four years that have elapsed since that article was published, the operative treatment by excision has found more and more favor. Excision has now been done in a considerable number of cases with encouraging results.

Undoubtedly, in a large proportion of cases the injection of Morton's fluid (iodine, gr. x., iodide of potassium, gr. xxx., glycerine, ℥ j) will effect a cure. Powers (New York *Medical Record*, July, 16, 1892, p. 64) has tabulated 15 cases collected since the Clinical Society's Report, with 4 deaths, giving a mortality of 26.66 per cent. He has also tabulated 34 cases of excision, from which he deducts 3, which were indefinite as to the cause of death, leaving 31 cases, with 24 recoveries and 7 deaths, a mortality of 22.58 per cent.

Were all the cases collected the probabilities are that the mortality would be about the same as, or possibly a little less than that of the method by injection of Morton's fluid; but as the technique improves it is fairly certain that the percentage of recoveries after excision will increase, and thus make this the favorite method of treatment. The age at which excision has been done has varied from immediately after birth (Walther, *Revue de Chirurgie*, April, 1892, 371) up to adult life, of which there have been collected in Powers' table 3 over twenty years of age, the oldest being Powers' own successful case at thirty years of age. Of course, but few cases survive to adult life.

Technique of Excision.—In case the tumor is a simple meningocele, an elliptical incision is made, preserving enough skin on each side to cover in the defect; the sac is then dissected down to its base, the serous membrane at the neck of the sac being sutured with the two serous surfaces apposed; or if very small, the neck of the sac may be ligated and the wound closed in the ordinary way. It is important to prevent the escape of the cerebro-spinal fluid, not so much on account of the immediate danger to life from its escape as to prevent a fistula, which may eventually become infected and be followed by meningitis; and to do this it is advisable that the lines of suture of the sac and of the skin be not opposite each other. How successful the treatment by excision may be in an apparently almost hopeless case is well shown in Robson's third case. She was a girl of sixteen, with a temperature of 102° F., restless, and moaning with intense headache and dilated and sluggish pupils. In twenty-six days, eighty-five ounces of cerebro-spinal fluid were removed from the sac by eight aspirations, with temporary relief, but finally, as she was evidently failing and must soon die, the excision was done, and in thirteen days she was entirely well.

Should the case be one of meningo-myelocele, the nerves will more commonly be found attached to the posterior surface of the sac, from which they should be dissected loose and replaced in the canal, the operation being completed as before. Whether the nerves are present in the sac and adherent to its walls or not, can sometimes be told by examination of the tumor by means of transmitted light from a candle held upon its opposite side, and while the surgeon looks through a cylinder of paper, the end of which must be closely applied to the skin. They are more commonly adherent on each side of the middle line, in which line sometimes a furrow exists. Their presence, which is found to be a fact in about sixty or seventy per cent. of the cases, is, as a matter of course, an added danger.

The firmer closure of the opening in the defective spine, however, is the direction in which the chief improvement has taken place from operative interference. Bayer (*Prager*

med. Wochenschr., 1890, p. 49) has loosened the muscles on each side of the spine and brought them together in the median line. In 1883, Robson, Jessop, and Hayes, of Rochester, N. Y. (*Trans. Clinical Soc. of London*, vol. xviii.), sought to close the cleft by using a strip of periosteum from a rabbit, the osteogenetic surface being turned undermost and the piece being sutured to the neighboring periosteum. Perrier (*Semaine Médicale*, May 18, 1892) refers to a case in which Berger inserted a plate of bone from the scapula of a young rabbit. The case was reported five months after the operation, the cure having persisted, though it was thought likely that the bone had become absorbed.

The most important modification, however, has been introduced by Dollinger, Senenko, and Bobroff, of Moscow (*Centralblatt für Chirurgie*, 1892, No. 22, p. 465). Dollinger, with bone forceps, divided the rudimentary portions of the arches of the fourth and fifth lumbar vertebræ, close to their bases, and pushed them close to the middle line, where he secured them by suture. Senenko did a similar operation in a sacral case, chiselling loose from each side a piece of bone two centimetres broad, leaving them, however, in connection with the soft parts at the upper and lower ends. After four months the posterior border of the sacrum showed a continuous bony surface. Bobroff, in October, 1891, operated in the following manner: After removing an elliptical portion of the skin covering the sacrum, several nervous cords of the cauda equina, and the lower end of the spinal marrow were dissected loose from the sac, and replaced in the vertebral canal. The opening was sufficiently large to admit the index-finger. Two incisions were next made along the upper border of the ilium, and the glutæus magnus was dissected from the bone. Bobroff then chiselled from the iliac crest a piece of bone, three centimetres wide, two centimetres long, and a little less than one centimetre thick. The piece of bone was not chiselled loose, but was turned over on a hinge formed by the erector spinæ muscle, so that the periosteal surface was next the cord, and the chiselled surface presented posteriorly. The edges of the defect were freshened, two bone sutures were placed in position, the wound being then closed as usual and the patient laid upon the abdomen. A drainage-tube was used. The cerebro-spinal fluid continued to escape for several days and then the flow ceased. After two months consolidation of the transplanted bone had taken place and the patient ceased to lie upon the abdomen. Five months after the operation he was in good condition.

This case is not only noteworthy by reason of the method of operating, but also on account of its results. From birth the boy had had incontinence of urine and fæces; after the operation for three months, first faradism was used, and later the galvanic current, to arouse the sphincters, which then began to act so that the boy was able to retain the contents of the rectum, not only when lying down, but in walking and running. The sphincter of the bladder, however, only served to retain his urine during the night or when he lay down in the day-time. As soon as he stood up the urine began to escape.

Bobroff proposes, in spina bifida of the lumbar and dorsal region, to fill the defect from adjacent ribs, chiselling off the outer lamellæ, but leaving them attached to the soft parts next the spine, and then to transplant them through a slit in the thickness of the erector spinæ instead of over its surface.

As a rule, as Powers points out, excision should be resorted to "in selected cases only—cases in which the general condition of the patient is good; in which paraplegia is absent; in which the vertebral fissure is of moderate extent and the communication between the sac and the canal is narrow." In other cases the injection of Morton's fluid would be the operation of preference, if any operation whatever is deemed wise. In *International Clinics* for October, 1891, I have reported two cases, one of cervical and one of sacral spina bifida, in which recovery from operative treatment followed, but the children died of enteritis.

II. Spinal Drainage for Tubercular Meningitis and Hydrocephalus.—In consequence of the uniformly fatal course of tubercular meningitis, and especially of the rapidly fatal intercurrent coma produced by dropsy of the lateral ventricles, and of the fact that there is often but little development of tubercle present, Wynter (*Lancet*, 1891, i., 931) proposed to drain away the cerebro-spinal fluid, not by tapping the ventricles, but by indirect drainage by puncturing the membranes of the cord in the lumbar region. He has reported four cases, all of which, however, resulted fatally. The first case operated on, in February, 1889, was a boy three years of age, who was comatose and with Cheyne-Stokes respiration. No anæsthetic was needed. The child was placed in a sitting position, a small incision was made in the skin, and a Southey tube and trocar were inserted until the lamina of the second lumbar vertebræ was reached. The point was then directed downward and pushed through the ligamentum subflavum, and then through the theca of the spine, when clear fluid at once welled up in the tube. A piece of rubber tubing was attached to the tube to carry off the fluid, the boy's breathing became regular, his color good, and he could swallow. Cessation of escape of the fluid was followed by death. The prick of the trocar could not be found. In the second case, a year later, Mr. Hulke removed the spine and right lamina of the second lumbar vertebra; punctured the theca with a knife and inserted a drainage-tube into the canal. The temperature dropped from 102° F. to the normal, but on the third day, when the aperture was closed and fluid ceased to escape, coma and strabismus set in and the child died the next day. In the third case Mr. A. Pearce Gould drained from the subdural space and stitched the margins of the theca to the edges of the wound. The child improved immediately on the escape of the fluid, but died four hours afterward. The fourth child also died in three hours.

Quincke (*Berliner klin. Woch.*, 1891, Nos. 38 and 39) reports ten similar operations for hydrocephalus, pressure being made upon the skull at the same time. One case was cured, in two the results were probably due to the other measures employed, in three there was temporary improvement; none of them died. In the *British Medical Journal* (Epitome, 1893, p. 81) he is said to have done twenty-two punctures. Quincke calls attention to the fact that the cord in infants extends to the third lumbar vertebra, and hence the puncture should be made in the third or fourth intervertebral space. In infants the cauda equina is in two lateral bundles separated by a space about five millimetres broad. The third and fourth lumbar spaces measure eighteen to twenty millimetres transversely, and ten to fifteen vertically; the depth of puncture to reach the cord in infants is about two centimetres, in adults about four to six centimetres.

III. Intra-spinal Division of the Posterior Nerve-roots for Inveterate Neuralgia.—In the New York *Medical Record* for February 9, 1889, Dr. Robert Abbe reports the case of a man forty-four years of age, who, about eighteen months before, began to suffer from neuralgia of the brachial plexus, for which first the nerves of the arm were stretched and later the arm amputated. Dr. Charles L. Dana proposed to the patient that the spinal cord should be exposed with a view to the removal of a tumor, or to remedy any inflammatory processes, if either of these lesions should be found present; and if neither of them was found, then for the purpose of cutting the posterior roots of the nerves involved. On December 31, 1888, Dr. Abbe carried out the suggestions of Dr. Dana, and removed half the posterior arch of the fourth and all of the arches of the fifth, sixth, and seventh cervical vertebræ. The dura was exposed over an extent of two inches, but no tumor was found. The intervertebral foramina were then explored with a curved hook; the sixth and seventh cervical nerves were hooked up gently so that a short loop of each was raised. This was done outside the dura, but inside the vertebral canal. The fifth nerve could not be raised without exciting hæmorrhage. The sixth and seventh nerves were then cut across just outside the dura, dividing in this manner both the motor and sensory roots. The wound was left open but packed with iodoform gauze. The pain, however, soon returned. Two days after the

operation, without ether, the wound was exposed and the dura slit up. It is noticeable that "the dura was scarcely at all sensitive to cutting," though Mr. Horsley has stated that in spinal operations profound anæsthesia is necessary during this step on account of its extreme sensibility. The posterior roots of the seventh and eighth nerves were divided within the dura, which was then sutured with catgut and the entire wound closed. His pain changed in character but soon returned, and Dr. Abbe writes me (January, 1893) that he "still has considerable neuralgia, if his statements can be taken for truth." Since then Abbe has reported a second case (New York *Medical Record*, July 26, 1890), in which, within the dura, he excised the posterior roots of the sixth, seventh, and eighth cervical and the first dorsal nerves. As in the former case, temporary relief was obtained. But though in each case the anæsthesia of the parts supplied by these nerves was persistent, the pain has returned. The condition of the second case, Abbe writes me, is practically the same as in that of the first. This is the more curious, inasmuch as we know that in nerves of sensation the Wallerian degeneration proceeds centrally and should have destroyed the central diseased ends of the nerve-fibres. Abbe suggests that the cutting of the fifth nerve root might have done more good. It has seemed to me that the "pain habit," if I may so call it, may be so established in these cases that an earlier rather than a more extensive operation would promise better results. Abbe's own opinion, as expressed in his note to me, is that "the operation is a safe one, and if the hysterical element can be eliminated from any proper case it should be tried still further, inasmuch as it cannot disable the arm in the slightest degree," the motor roots being left intact—an opinion in which I fully concur.

Dr. W. H. Bennett ("*Medico-Chirurgical Transactions*," 1889, lxxii., p. 329) also reports the case of a man, the subject of syphilis, who had suffered agonizing pain in the left leg, and later in the latissimus dorsi and erector spinæ muscles, with violent spasms. An incision had first been made over the tibia, later the leg was amputated at the knee, followed by stretching, and finally, excision of the sciatic nerve, all to no purpose. Mr. Bennett, by an incision six inches long, with its centre at the eleventh dorsal spine, removed the laminæ of the ninth, tenth, and eleventh dorsal and first lumbar vertebræ. The nerves divided were the lower four lumbar, division of the nerves causing arrest of the pulse, which returned upon gentle pressure on the cord with a warm sponge. Then the first two sacral nerves were divided, followed by a similar effect upon the heart. Bennett discovered later that he had not divided the second lumbar, as he had thought at the time of operation. On the fifth day the patient was comfortable, no pain existing, though the spasms recurred. By the tenth day the wound was healed. On the eleventh day the man suddenly died from cerebral apoplexy. The post-mortem showed sclerosis of the posterior root zone and of the columns of Goll.

Division of the posterior nerve-roots for inveterate neuralgia will probably take the same position as resection of the fifth nerve in trigeminal neuralgia. The operation is one of considerable difficulty, but not of excessive danger. It is, however, doubtful whether it will permanently remedy the disease, at least in some cases. As in trigeminal neuralgia, the peripheral operations are less dangerous, and at least for a time are efficacious, and it is probable that stretching or resection of the nerves involved, and sometimes amputation, would be justified before recourse is had to division of the nerve-roots, but the pain is occasionally so horrible that the patient will be willing to undergo any operation, no matter what its magnitude or danger, in order to get relief. Such an operation should manifestly be reserved for such cases, which fortunately are extremely rare, but, as already suggested, it should not be so long delayed after recurrence that the pain habit has become firmly established.

IV. Spinal Hæmorrhage.—Spinal hæmorrhage may be either a hæmato-myelia, *i.e.*, hæmorrhage into the spinal cord itself; or hæmato-rhachis, that is, hæmorrhage in connection with the spinal membranes.

Hæmato-myelia sufficient to cause symptoms is, according to Gowers, a very rare disease and does not admit, of course, of surgical treatment. Mr. Thorburn, however, ("Surgery of the Spinal Cord," p. 62), has pointed out the fact that, especially in the cervical region, hæmatomyelia unaccompanied by any evidence of injury to the spine itself is relatively frequent, having been found in six out of the twenty-one cases of injury to the spine he reports. "The symptoms will depend upon whether the lesion is a 'destroying' or a 'compressing' one, the former being permanent, the latter more or less temporary. A 'destroying' hæmorrhagic lesion produces atrophic paralysis, and possibly persistent anæsthesia in the distribution of some of the roots of the brachial plexus. The 'compressing' lesion may cause more or less complete paralysis and anæsthesia below its level, with retention of urine and fæces, priapism, contraction of the pupil, and other symptoms, which as a rule soon subside, probably leaving only some spastic symptoms in the lower limbs" (Thorburn). Thorburn attributes the lesion not to concussion, but to a diastasis with recoil. The region in which hæmato-myelia is found is between the fifth cervical and first dorsal nerves, corresponding to the bodies of the fourth, fifth, and sixth cervical vertebræ—that is, the summit of the arch formed by the cervical curve and the point at which acute flexion of the neck would produce its worst results.

In *hæmato-rhachis* the blood may be found outside of the membranes (extra-dural hæmorrhage), under the dura (subdural hæmorrhage), or under the arachnoid (subarachnoid hæmorrhage). In the extra-dural or extra-meningeal form the amount of blood is rarely sufficient to produce compression. In subdural hæmorrhage it may be quite extensive, and may pass almost from one end of the cord to the other. Neither form of hæmorrhage is, as a rule, amenable to surgical intervention, though Mills has suggested the possibility of trephining at two points to secure suitable drainage.

V. Gunshot Wounds of the Spinal Cord.—As a rule, modern surgery is so far in advance of that of the past that gunshot wounds involving the cord should be operated on, unless, as Vincent (*Rev. de Chir.*, February, 1892, p. 89) states, other lesions of a probably fatal character would forbid interference. As he states, gunshot wounds of the cord may be divided into three classes:

1. Those in which the cord is compressed by extravasation of blood, by fragments of bone, or by the projectile lying outside of the medullary canal. In this class, by removal of the source of compression we shall at least do no harm, and shall probably improve the condition of the patient.

2. If the projectile has passed through the spine, injuring the cord in its track, as the diagnosis of the amount of injury cannot be made without an operation, it would be best, as a rule, to explore, unless other fatal and especially visceral lesions are present.

3. If the projectile lodge in the spinal canal, an operation should certainly be done on account of the almost absolutely certain meningitis and myelitis, followed by cystitis, bed-sores, and death.

VI. Laminectomy for Pott's Disease.—The first laminectomy for Pott's disease seems to have been done by Jackson, of Sheffield (*Brit. Med. Journ.*, 1883, i., p. 812); but the modern surgery of Pott's disease really dates from the case of Macewen (*Lancet*, 1885, i., 881), when he operated on a case of paraplegia with incontinence of urine and fæces, due to a connective-tissue tumor at the seat of angular curvature of the spine. In this boy, nine years of age, between the theca and the bone was found a fibrous neoplasm one-eighth of an inch in thickness, firmly attached to the theca and covering two-thirds of its circumference. After this was dissected away the cord was able to expand backward, and pulsation, which had been absent, showed itself, especially opposite the fifth dorsal vertebra. Twenty-four hours after the removal of the pressure the limbs had lost their livid color and were warm; the spastic rigidity was greatly lessened; the perception of tickling the soles had returned, and that of touch was improved. Movement was first observed eight

days later, and soon after this he had perfect control over the sphincters. After six months he was able to go about without support. Five years afterward he could walk three miles; he attended school regularly, joining in all the games, including even foot-ball.

A second and more aggravated case (*Brit. Med. Journ.*, 1888, ii., 308), operated on in 1884, by the same surgeon, showed a slight tumor with organic changes in the cord, which had shrunk to about half its normal dimensions. In ten hours after the operation the limbs had lost their lividity and felt warm. From the fourth day the patient obtained control over her bladder and rectum; six weeks after the operation she could move her limbs freely, and two months after, she walked a quarter of a mile and was able to perform light duties in the house.

Three other similar cases were operated on, one of which was successful, but the other two died. Besides these cases Macewen reported the evacuation of an abscess in the posterior mediastinum, which was pressing on the heart and bronchi. This case was also completely successful. Another similar and striking illustrative case is reported by Southam (*Brit. Med. Journ.*, 1892, i., 655), in a child three and a half years old, all four extremities being so paralyzed that the patient lay helpless in bed with incontinence of both urine and fæces. In this case, at two operations three months apart, he removed the laminæ from the fourth cervical to the first dorsal vertebra inclusive, and removed a quantity of granulation-tissue. But little improvement was noticed for nine months after the second operation; then—a most important point of encouragement—the child began to improve, and, when reported two years later, could walk without assistance and had control over the sphincters.

The source of the nervous symptoms seems not generally to be the mere curvature of the spine, nor an acute myelitis, but the pressure caused either by fungous masses of granulation-tissue over the bodies of the vertebræ by inflammatory swelling, but oftenest by a chronic pachymeningitis, or by the accumulation of pus. For instance, W. Arbuthnot Lane (*Lancet*, 1891, ii., 989), reports eleven cases of Pott's disease in which the compression in all but one was caused by an abscess. In none of these were there any fibrous neoplasms such as are described by Macewen. In such cases death follows either as the result of pulmonary complications, or more frequently from cystitis and renal complications, bed-sores, pain, sleeplessness, etc. In all of Lane's cases the large amount of disease would have precluded a cure by anchylosis. He urges, therefore, that "every case of paraplegia due to spinal caries should be operated on with as little delay as possible." In view, however, of published clinical results, especially as shown by Lloyd (*Annals of Surgery*, October, 1892, 289), who has tabulated seventy-five cases of laminectomy for Pott's disease, this opinion seems too sweeping if taken without reservation. Thus Meyers has reported recovery from paraplegia without operation in fifty-five per cent. of 218 cases; Gibney, fifty per cent. in 58 cases; Taylor and Lovett, ninety per cent. in 19 cases; and Sayre, ninety per cent. in 38 cases. The views of Burrell and Bullard and of Kraske seem to be the more reasonable. "So long as we have reasonable or even moderate chances of recovery without operation," say the former authors, "we do not believe it advisable or justifiable, in the present condition of spinal surgery, to perform so serious an operation as the resection of the laminæ." Kraske's rule for interference is well expressed. "It is necessary before operating to have exhausted all other methods of treatment. I would say, interfere when a paralysis of the bladder is established; this is the one symptom which is so serious as to justify everything" (Lloyd), to which Lloyd adds that "the first sign of degeneration of the cord should indicate immediate operation." It will be especially observed that ordinary cases of mere curvature from Pott's disease are excluded, and only those in which paraplegia with all its dire evils has resulted from the caries, should be considered suitable for operation, and then only with the limitations already stated. If there are other tubercular complications, operative interference of course is contra-indicated.

It will be observed that the cases above referred to fall into two categories: First, the cases of paraplegia from pressure, either by masses of granulation-tissue which may arise from the vertebræ within the spinal canal, or by the thickening which results from pachymeningitis—a thickening which, for instance in Macewen's case, amounted practically to a tumor so far as pressure on the cord is concerned; secondly, cases of paraplegia as a result of pressure on the cord from abscesses resulting from the breaking down of the granulation-tissue. Cases of paraplegia from either of these lesions, provided they fulfil the conditions already mentioned, may be treated by laminectomy, with removal of the neoplasm, the granulation-tissue, the pus, the carious bone, etc., by the usual means employed in such cases. (*Vide infra, Technigue*, p. 824.)

Besides these there are many cases of abscesses in Pott's disease in which modern surgery has of late achieved notable improvements in the way of preventing the later lesions which they induce in the cord, lesions to which we may properly here make brief allusion. Until within a few years surgical interference has been limited to evacuation and drainage of these abscesses at their lowest point—*e.g.*, usually on the thigh below Poupart's ligament—with or without curetting, or injection of iodoform in ether, or an emulsion of iodoform in olive-oil. This left the source of the evil—the carious vertebræ—untouched, and also very imperfectly treated the abscess. Mr. Treves, in June, 1884 (*Med.-Chir. Trans.*, vol. lxvii.), urged the evacuation of psoas abscess in the loin, combined with the removal of the carious and necrosed bone by the usual means employed elsewhere. In his "Manual of Operative Surgery," vol. ii., p. 731, 1892, he has described his improved method.

In the cervical region such retro-pharyngeal abscesses are usually accessible through the mouth, and the bone can also be treated by the same route. Burckhardt (*Centralbl. f. Chir.*, 1888, No. 4) has advocated an external incision at the inner border of the sterno-cleido-mastoid, reaching the abscess by the inner side of the sheath of the vessels, and Kramer (*Centralbl. f. Chir.*, 1892, No. 12) has successfully carried out Burckhardt's proposed operation with ease. Chiene, as early as 1877, advocated a similar operation on the outer border of the sterno-cleido-mastoid. These operations have the advantage, of course, of permitting more thorough antisepsis than the oral route, but the mortality of the latter has been very small. In abscesses in the cervical region, accessible with difficulty by the mouth, however, these methods of operating will prove of greater value than that by the mouth.

In the dorsal region the methods of Vincent (*Rev. de Chir.*, April, 1892, 273) and Schaefer (*Journal of the Amer. Med. Assoc.*, December 19, 1891, 943) are applicable.

VII. Fractures and Dislocations of the Spine.—Of the many distressing, painful, and fatal accidents to the human body, fractures and dislocations of the spine are among the most pitiful. Though either may occur independently, they are often combined, when the compound name of fracture-dislocation is appropriately used. The injury to the bone, though it may be extensive, is really the least important element in the case. It is the injury to the cord which is of such vital importance, since this interferes with motion and sensation, causes loss of control of the bladder and the rectum, and is followed very frequently and very speedily, often within twenty-four or forty-eight hours, by large bed-sores, especially over the sacrum; these bed-sores not only leading to extensive exposure of the bones, but often to septic complications, which of themselves would terminate life, even though no other lesions existed. The amount of injury of the cord varies very greatly. Sometimes, especially in the lower part of the cervical region, the bending of the neck may be so extreme as to produce mechanical destruction of the cord without any fracture, and with only temporary diastasis of the bones, which spring back into place after having injured the cord. In other cases the displacement may persist, and be so severe that the cord may be reduced to a pulp or even torn into shreds. The extent of the injury cannot be

ascertained with accuracy in many cases, until either an exploratory operation or the post-mortem reveals it. In dislocation, of course, the lesion will be at the intervertebral cartilages. In fracture there may be fracture and displacement of the laminæ which may produce compression of the cord, and fragments of bone may be driven into the cord; or there may be fracture of the vertebral bodies, which may be greatly displaced and produce direct pressure on the cord, or the articular and transverse processes may be broken. It is especially to be observed that the external deformity may be very slight, and yet the injury to the cord may be very great. This, of course, is due to the fact that the external deformity only shows the lesions of the laminæ and spinous processes. The lesions of the bodies and articular processes are so deep that their extent cannot be determined by an examination of the back. The reparative powers of the spinal cord are often surprisingly great, so that even after severe crushing it may to some extent, and occasionally to a large extent, recover its functions; hence the encouragement for surgical interference in order to place the cord in the most favorable conditions for recovery.

The distinction between total and partial transverse lesions of the cord is a very important one, and has been studied by Bastian (*Med.-Chir. Trans.*, 1890, lxxiii., 151), Thorburn (*Manchester Med. Chron.*, 1892, xvi., 73, and "Surgery of the Spinal Cord"), Herter (*Journ. of Nerv. and Ment. Dis.*, June, 1891), and others, especially with reference to the condition of the reflexes as an index to the extent of the lesion, whether it be partial or total, and therefore whether it be advisable to operate or not. The generally expressed opinion of the authors named is that in complete transverse destructive lesions of the cord there will be complete paralysis of the muscles, complete anæsthesia, and also complete and permanent abolition of the knee-jerk and other deep reflexes on both sides; but that in partial destructive transverse lesion of the cord the paralysis of the muscles and also the anæsthesia will be incomplete, and the deep reflexes will be either normal or exaggerated. The visceral reflexes, especially those of the bladder and rectum, obey the same rule as the deep reflexes, but the superficial reflexes do not follow the same rule as absolutely. Hence, Thorburn, Herter, and others would condemn an operation if immediately after an accident the knee-jerk on both sides is absent. This disapproval, in the light of experience, certainly seems to be too positive. Thus Schede (*Ann. of Surg.*, Sept., 1892, 231) reports the case of a man who had fallen from a height and fractured the fifth and sixth dorsal vertebræ, with complete paraplegia and anæsthesia of the lower extremities. The patellar reflexes were absent. The next day bed-sores were beginning over the gluteal region. Sixteen hours after the accident Schede operated and removed the fragments which were pressing on the cord, the dura being uninjured, but the cord being soft and fluctuating. In two days the patient's symptoms began to improve. The knee-jerks became increased, with ankle clonus on the right side, and the superficial reflexes scarcely increased, excepting those of the footsole. When reported the functions of the bladder and rectum were normal, and the patient was able to walk about without support or pain. His nutrition was excellent, and two months after his discharge he was in first-rate health. Had the rule stated above been adhered to, not to operate when the knee-jerks immediately after the accident are abolished, unquestionably this patient would have died from the myelitis following compression and injury of the cord.*

Thorburn ("Surg. of Sp. C.," p. 94; *Brit. Med. Jour.*, '88, ii., 881) also reports a case of recovery after traumatic paraplegia, with absence of knee-jerks and superficial reflexes, from dislocation of the second lumbar vertebra, in which sensation returned and movements of the knee-jerks were normal, those of the ankle being limited to extension; he had perfect control over the bladder, and nearly two years after the operation was able to walk three miles, with short intervals of rest, and was generally improving. It is true that in this case the very upper limit of the cauda equina was compressed, but this was not known to a certainty until the operation revealed it, and, moreover, the blunting of sensation over the genitals showed that the lower two segments of the cord had been at least to some extent injured. Very recently, at the Jefferson Hospital, I assisted my colleague, Prof. Forbes, in a laminectomy for an old fracture-dislocation in the dorso-lumbar region, in which the knee-jerks had been absent for eighteen months and returned within a week after the operation.

If no operation is done and the pressure still remains, the cord will not only degenerate, a process which begins as early as the third or fourth day, but a traumatic myelitis will follow without any possible doubt. Even if the pressure be removed myelitis will occur in the majority of cases, but the cases quoted and others show that an unexpectedly good result may sometimes be obtained, even in apparently hopeless cases.

A sharp distinction must be drawn between lesions of the cord itself and of the nerve-roots, which are practically peripheral nerves. The nerves, as is well known, resist trauma remarkably well, and recover from it to a surprising extent. This especially emphasizes the wisdom of operation in such lesions in the region of the cauda equina (that is to say, fractures below the level of the first lumbar vertebra), which are followed by paralysis of these nerves. These are entirely peripheral nerves, and their lesions should be treated precisely like lesions of peripheral nerves in other parts of the body. If they are merely contusions or bruises the symptoms will be immediate but temporary, and recovery follows; but if the symptoms persist the cause must be a permanent one and should be removed, whether it be pressure from a displaced bone or from cicatricial tissue, resulting from such an injury. The rule which has received the widest commendation of surgeons is that of Lauenstein (*Centralbl. f. Chir.*, 1886, No. 51, p. 888), that if after from six to ten weeks there is incontinence of urine and fæces, with cystitis and bed-sores, little is to be hoped for from nature's efforts, and an operation is justifiable. Horsley (*Brit. Med. Journ.*, December 6, 1890), however, is much more emphatic, and says: "In all cases where displacement or crepitus indicates compression, and where extension directly after the accident fails to reduce the displacement," we should operate if there are symptoms showing interference with the functions of the cord. In view of the early degeneration of the cord if the pressure be not relieved, of the great mortality in such cases, and of the rare but undoubted instances of good results following early operation, the tendency of modern surgeons is toward earlier rather than later interference. Schede's case already cited is a good example, and Golding Bird (*Brit. Med. Journ.*, 1891, i., 1124) has reported another of operation on the second day after a fracture of the eleventh and twelfth dorsal laminæ, causing almost complete paraplegia from compression of the cord by the displaced laminæ, and in eighteen days the patient seemed quite well. Moreover, it must be remembered that a definite conclusion should not be reached nor the cases be reported too early. Not only after operations in fracture-dislocations, but in any operations on the spine, improvement may begin late and continue slowly but surely for many months (cf. p. 823). Hence no case should be despaired of until at least a year has elapsed after the operation.

The determination of the level at which the lesion exists is a very important one, and to some extent is not yet capable of so exact a solution as we could wish. Three means exist for ascertaining this level: first, the determination of the extent of the motor paralysis; secondly, of the area of the sensory paralysis; and thirdly, the presence or abolition of the reflexes connected with each segment. From these three phenomena we can judge what nerves, and therefore what spinal segments, are involved. For this purpose the spinal cord may be considered as a series of segments placed one on top of another like a pile of checkers, these segments corresponding to the nerves which arise from them. Thus the fifth cervical segment would correspond to that segment of the spinal cord from which the fifth cervical nerve-roots originate,

* See a similar case by Phelps and Hammond (Jour. Nerv. and Ment. Dis., July, 1893, 472 and 478).

the sixth segment to the source of origin of the sixth nerve-roots, and so on. The following table of localization of the functions of the segments of the spinal column gives in the first column the various segments of the spinal cord which have been investigated; in the second, the muscles supplied by the nerve or nerves arising from each segment; thirdly, the reflex which has its origin in such a segment; and fourthly, the area of sensation, that is, the area of skin supplied by such nerves.

LOCALIZATION OF THE FUNCTIONS OF THE SEGMENTS OF THE SPINAL CORD.

Segment.	*Muscles.*	*Reflex.*	*Sensation.*
Second and third cervical.	Sterno-mastoid. Trapezius. Scaleni and neck. Diaphragm.	*Hypochondrium* (?) (third to fourth cervical). Sudden inspiration produced by sudden pressure beneath the lower border of ribs.	Back of neck and of head to vertex. (Occipitalis major, occipitalis minor, auricularis magnus, superficialis colli, and supraclavicular.)
Fourth cervical.	Diaphragm. Deltoid. Biceps. Coraco-brachialis. Supinator longus. Rhomboid. Supra- and infraspinatus.	*Pupillary* (fourth cervical to second dorsal). Dilatation of the pupil produced by irritation of neck.	Neck. Shoulder, anterior surface. Outer arm. (Supraclavicular, circumflex, musculo-cutaneous or external cutaneous.)
Fifth cervical.	Deltoid. Biceps. Coraco-brachialis. Brachialis anticus. Supinator longus. Supinator brevis. Deep muscle of shoulder-blade. Rhomboid. Teres minor. Pectoralis (clavicular part). Serratus magnus.	*Scapular* (fifth cervical to first dorsal). Irritation of skin over the scapula produces contraction of scapular muscles *Supinator longus* (fourth to fifth cervical). Tapping the tendon of the supinator longus produces flexion of forearm.	Back of shoulder and arm. Outer side of arm and forearm to wrist. (Supraclavicular, circumflex, musculo-cutaneous or external cutaneous, internal cutaneous, radial.)
Sixth cervical.	Biceps. Brachialis anticus. Subscapular. Pectoralis (clavicular part). Serratus magnus. Triceps. Extensors of wrist and fingers. Pronators.	*Triceps* (sixth to seventh cervical). Tapping elbow tendon produces extension of forearm. *Posterior wrist* (sixth to eighth cervical). Tapping tendons causes extension of hand.	Outer side and front of forearm. Back of hand, radial distribution. (Chiefly musculo-cutaneous or external cutaneous, internal cutaneous.)
Seventh cervical.	Triceps (long head) Extensors of wrist and fingers. Pronators of wrist. Flexors of wrist. Subscapular. Pectoralis (costal part). Serratus magnus. Latissimus dorsi. Teres major.	*Anterior wrist* (seventh to eighth cervical). Tapping anterior tendons causes flexion of hand. *Palmar* (seventh cervical to first dorsal). Stroking palm causes closure of fingers.	Radial distribution in the hand. Median distribution in the palm, thumb, index, and one-half middle finger. (Musculo-cutaneous or external cutaneous, internal cutaneous, radial, median.)
Eighth cervical.	Triceps (long head) Flexors of wrist and fingers. Intrinsic hand muscles.	.....	Ulnar area of hand, back, and palm, inner border of forearm. (Internal cutaneous, ulnar.)
First dorsal.	Extensors of thumb Intrinsic hand muscles, Thenar and hypothenar muscles.	.....	Chiefly inner side of forearm and arm to near the axilla. (Chiefly internal cutaneous and nerve of Wrisberg or lesser internal cutaneous.)
Second dorsal.	.....	.....	Inner side of arm near and in axilla. (Intercosto-humeral.)
Second to twelfth dorsal.	Muscles of back and abdomen. Erectores spinæ.	*Epigastric* (fourth to seventh dorsal). Tickling mammary region causes retraction of the epigastrium. *Abdominal* (seventh to eleventh dorsal). Stroking side of abdomen causes retraction of belly.	Skin of chest and abdomen, in bands running around and downward corresponding to spinal nerves. Upper gluteal region. (Intercostals and dorsal posterior nerves.)
First lumbar.	Ilio-psoas. Rectus. Sartorius.	*Cremasteric* (first to third lumbar). Stroking inner thigh causes retraction of testicle.	Skin over groin and front of scrotum. (Ilio-hypogastric, ilio-inguinal.)
Second lumbar.	Ilio-psoas. Sartorius. Quadriceps femoris	.....	Outer side of thigh. (Genito-crural, external cutaneous.)
Third lumbar.	Quadriceps femoris Anterior part of biceps. Inward rotators of thigh. Abductors of thigh.	*Patellar* (third to fourth lumbar). Striking patellar tendon causes extension of leg.	Front of thigh. (Middle cutaneous, internal cutaneous, long saphenous, obturator.)
Fourth lumbar.	Abductors of thigh Adductors of thigh Flexors of knee. Tibialis anticus. Peronens longus.	*Gluteal* (fourth to fifth lumbar). Stroking buttock causes dimpling in fold of buttock.	Inner side of thigh, leg, and foot. (Internal cutaneous, long saphenous, obturator.)
Fifth lumbar.	Outward rotators of thigh. Flexors of knee. Flexors of ankle. Peronei. Extensors of toes.	*Achilles tendon* (fifth lumbar to first sacral). Over-extension causes rapid flexion of ankle, called ankle clonus.	Back and outer side of leg; sole; dorsum of foot. (External, popliteal, external saphenous, musculo-cutaneous, plantar.)
First and second sacral.	Flexors of ankle. Extensors of ankle. Long flexor of toes. Intrinsic foot muscles.	*Plantar* (fifth lumbar to second sacral). Tickling sole of foot causes flexion of toes and retraction of leg.	Back and outer side of leg; sole; dorsum of foot.) (Same as fifth lumbar.)
Third, fourth, and fifth sacral.	Glutens maximus. Perineal. Muscles of bladder, rectum, and external genitals.	Vesical centres. Anal centres.	Back of thigh, anus, perineum, external genitals. (Small sciatic, pudic, inferior hemorrhoidal, inferior pudendal.)
Fifth sacral and coccygeal.	Coccygeus muscles.	.....	Skin about the anus and coccyx. (Coccygeal.)

This table I have taken from Mills (*Therap. Gaz.*, 1889, p. 314). It is founded on one by M. Allen Starr (*Am. Journ. of the Med. Sci.*, May, 1888, p. 464). It must be understood, however, that further observations will very likely necessitate changes in some of its details. Similar tables for the different regions may be found in Thorburn's "Surgery of the Spinal Cord," pp. 77 and 111.

Mr. Thorburn has called especial attention to what he terms the "fifth root group" of muscles, and to the almost pathognomonic postures assumed by the patient who has had the fifth cervical nerve crushed and its muscles paralyzed, in contrast to the different position of the arms assumed in cases of lesion below this point. The fifth cervical nerve supplies chiefly the biceps, the brachialis anticus, the deltoid, and the supinators. If these muscles are not paralyzed, that is, if the fifth cervical nerve is uninjured and the lesion exists at a lower level, even so close as the sixth nerve, the deltoid will abduct the elbow, the infra-spinatus (supplied by the fourth nerve) will rotate the humerus externally, and the biceps, brachialis anticus, and supinator longus will flex and supinate the forearms, so that the patient will lie with his arms in the characteristic attitude shown in Fig. 585 and, in the right arm, in Fig. 586. That is to say, if the fracture be below the fifth cervical nerve

there will be abduction of the arm, elevation and external rotation of the humerus, with flexion of the elbow and supination of the hand. If, however, the lesion involves the fifth cervical nerve, the deltoid being paralyzed, the elbow will lie next the body, the biceps and brachialis and supinator longus being paralyzed, the

FIG. 585.—Peculiar Attitude of a Patient in whom the Fifth Cervical Nerves had been Crushed. (Thorburn.)

forearm and hand will lie prone on the chest, as is well shown in the left arm in Fig. 586, in which the fifth cervical nerve has been injured on the left side only. At other levels than these there will be no characteristic posture, but the site of the injury can be ascertained by determining what muscles are paralyzed, and therefore what nerves are involved. It is of great importance that in future cases, therefore, both surgeons and neurologists should not merely use general terms, but mention in detail the individual muscles which are paralyzed. In this way only can we hereafter determine the exact value of each spinal segment. We must remember also that the muscular paralysis will vary at different periods after the accident, and that it is of the greatest importance to determine, not only the initial paralysis, but also from day to day the alteration of such paralysis, due to either recovery, or, in destructive cases, to the upward march of the myelitis.

Secondly, the lesion can be determined to some extent by the anæsthetic cutaneous area. In the cervical region the table just given will enable us to arrive at a moderately accurate determination of the nerves involved from the area of anæsthesia found clinically, but it is to be regretted that as yet there are no charts, constructed from well-recorded cases, to guide us in this determination of the level of the lesion from the anæsthesia. In a general way, as Mr. Thorburn indicates, the outer parts of the limb correspond to the upper nerve-roots, and the inner to the lower. When we reach the dorsal region of the cord, the area of anæsthesia is as a rule nearly horizontal, and encircles the trunk if the lesion be bilateral.

It is important to remember, however, that the foramina of exit of the spinal nerves and the level of the segments of the cord from which they arise do not correspond. A reference to the well-known cut of Dr. Gowers (Fig. 587) shows how far, especially as we go down the cord, the individual nerves pass downward within the spinal canal before making their exit. Thus the fifth dorsal nerve originates opposite the body of the fourth dorsal vertebra, the twelfth dorsal nerve opposite the eleventh dorsal vertebra; while the second lumbar nerve originates opposite the body of the twelfth dorsal vertebra. In fact, the five sacral and the coccygeal nerves are all crowded together at their origins in the small region opposite the bodies of the twelfth dorsal and first lumbar vertebræ. As a consequence of this difference of level of the segment from which it originates and the parts supplied by the nerve, the region of anæsthesia as a rule will be considerably below the level of the nerve involved. In addition to this, between the area of complete normal sensibility and the area of anæsthesia there is a region of varying breadth in which the sensibility is perverted, called the region of paræsthesia or dysæsthesia.

FIG. 586.—Instance of a Case where the Fifth Cervical Nerve had been Injured on the Left Side only. (Thorburn.)

Starr (*Am. Journ. of the Med. Sci.*, July, 1892, p. 15) has made a most careful study of the condition of local anæsthesia as a guide to the diagnosis of lesions of the lower spinal cord, that is, from the second lumbar to the fifth sacral segments of the cord; and has combined the observations into two diagrams (Figs. 588 and 589) which will prove of the greatest value as a foundation for future studies. His conclusions may be summarized as follows:

In the spinal cord the centres of control of the bladder and rectum are always affected together, and must therefore be adjacent. Control over these sphincters is lost when the lower three sacral segments are involved, and probably the centres which control them lie in the lowest two segments. Loss of control over the sphincter ani is best determined by the introduction of the finger, which will meet with no resistance when the sphincter is paralyzed. The sphincter of the bladder is not permanently relaxed, for constant dribbling does not take place, but there is only intermittent though unconscious dribbling as soon as a few ounces of urine collect. Retention of urine is much more liable to occur when the lesion lies at a higher level. If, therefore, in a case of paraplegia the mechanism of the bladder and rectum is not interfered with, it is a proof that the lesion has not destroyed the lower sacral segments of the cord. This fact, with a careful

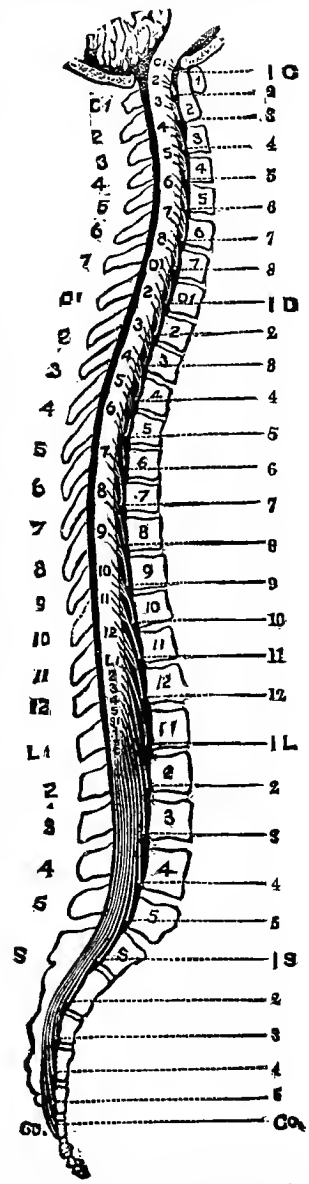

FIG. 587.—Diagram Showing the Relations between the Different Levels of the Segments of the Spinal Cord and the Nerves Originating from them, and the Levels of the Spines and Bodies of the Vertebræ between which they Emerge. (Gowers.)

determination of the area of anæsthesia, may enable us to make an exact diagnosis.

Figs. 588 and 589 show the cutaneous areas of anæsthesia which are caused by lesions of the nerves indicated. Each area of anæsthesia includes the smaller ones within it. The different zones are numbered in the illustrations, as follows:

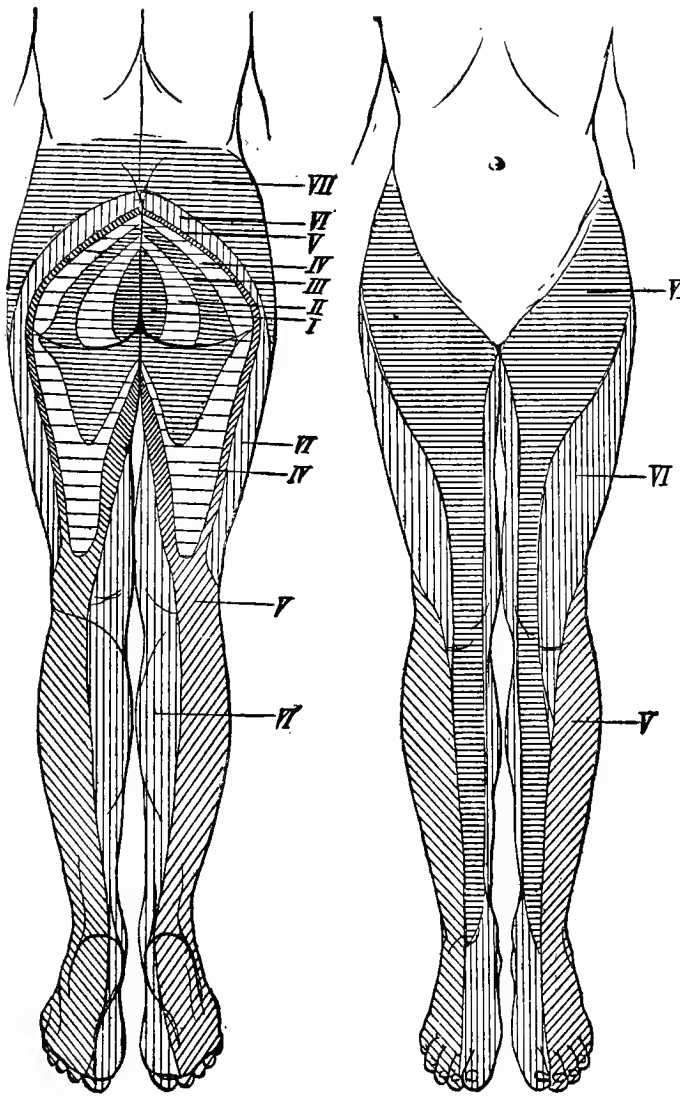
I. The first zone is supplied by the fifth sacral segment and includes the perineum, the posterior part of the scrotum in males, the vagina in females, and also the mucous membrane of the rectum.

II. The second zone, supplied by the conus medullaris and the fifth and fourth sacral segments, is heart-shaped, with the point up, and includes the entire scrotum and the posterior surface of the penis, the mucous membrane of the urethra in males, the entire genitals of the female except the outer surface of the labia majora and the mons veneris.

If the genital organs escape the case is one of functional and not of organic paraplegia.

III. The third zone is supplied by the fifth, fourth, and third sacral segments, and involves not only the buttocks, but extends down the back of the thighs. This has been named the "saddle-shaped" area, as it coincides with that part of the body which is in contact with the saddle in riding.

IV. This corresponds to the first and second sacral segments and is similar to the third, except that it is larger in extent.



Figs. 588 and 589.—Areas of anæsthesia resulting from lesions at various levels of the spinal cord, from sacral V, to lumbar II. (After Starr.)* I, Sacral v.; II, Sacral iv.; III, Sacral iii.; IV, Sacral i.; V, Lumbar v.; VI, Lumbar iii.; VII, Lumbar ii.

V. The fifth zone corresponds to the fifth lumbar segment.

VI. The sixth zone corresponds to the third lumbar segment. This may hereafter be separated into two parts corresponding to lesions of the fourth and third lumbar segments. As yet the number of recorded cases is insufficient for this distinction.

VII. The seventh zone involves the four lower lumbar segments. It will be observed that the abdominal wall is not anæsthetic in lesions of this segment. It is only when the first lumbar segment of the cord is involved that the anæsthesia extends to the abdominal wall.

Above the level of the second lumbar segment the zone of anæsthesia extends around the body in a girdle.

It is impossible at present, by the area of anæsthesia, to distinguish the lesions of that part of the cord from which the nerves of the cauda equina arise from lesions of the cauda itself. If the fracture or dislocation, however, is below the first lumbar vertebra, at which level the cord ends, the lesion must be of the cauda itself.

The muscular paralysis is very slight in lower cord lesions, being confined to the perineal muscles when the lesions are at or below the second sacral segment. It involves the anterior and posterior tibial muscles when all the sacral segments are involved, and only involves the movement of the hip-joint when the entire lumbar region is affected. In lesions of the cauda, on the other hand, pressure on nerve-roots is often sufficient to produce widespread paralysis when sensation is but slightly affected (Starr).

It has been thought that sensations of touch, temperature, and pain not being equally destroyed, was an evidence of lesions of the cord as distinguished from one of the cauda, but Starr has shown that this point is not well taken.

The table on page 819 shows the origin and distribution of the reflexes; these should be exactly observed and recorded in each case.

Eye Symptoms.—Only in lesions at and above the second dorsal would we expect any pupillary trouble, the cilio-spinal centre being involved. The sympathetic or radiating fibres of the iris being paralyzed, the pupil will then be smaller and immobile. Mr. Thorburn has shown that the eye-ground gives but little information so far as we now know. There may be a haziness of the disk, with want of definition of its margins and slight distention of the retinal veins, coming on the third or fourth day, and persisting for three or four weeks. Atrophy of the optic nerve does not take place.

Dangers of Operation.—Mr. Horsley has called attention to five of these: 1. Hæmorrhage. 2. Difficulty in clearing the neural canal. 3. Physical difficulties in treating the fractured vertebræ. 4. The hopeless nature of the damage to the spinal cord; and 5, septic infection; to which White has added 6, the danger of anæsthesia in the prone position, with paralysis of the abdominal muscles. The last is a real danger, and one of my own cases

* M. Allen Starr: Am. Journ. M. Sci., July, 1892.

came near dying from apnœa in consequence of anæsthesia even in the dorsal position, before I began the operation. He bore the operation, however, very well in spite of this. Sepsis is also a real danger which ought to be overcome by modern antiseptic methods. Whether the damage to the spinal cord, if extensive, makes the case hopeless or not is really the most important question, especially as the operation itself involves to a certain extent some additional disturbance and damage to the cord. Thorburn does not approve of operation, as a rule, inasmuch as he does not believe that it holds out much prospect of improvement. In those cases—and they constitute a majority—in which there is not found any serious narrowing of the vertebral canal, he says the operation is useless, as the whole mischief is already done. If the displacement of the bones is maintained, and the cord is permaneutly compressed, the damage to the cord is greater than in those cases just mentioned. Yet even in the more favorable conditions recovery rarely follows, and it is highly improbable that those in which the pressure persists will do any better after trephining. In other words, the damage done by the acute compression of the cord is usually irremediable, whether the pressure still remains or has been removed. On the other hand, Mr. Horsley says: "So far from its being unjustifiable to operate on the spine owing to the possibility of the cord being hopelessly damaged, it seems to me to be criminal not to operate." As is so often the case the truth seems to lie between these two extreme and diametrically opposite views.

The other three dangers already alluded to may be practically disregarded, for, by the modern technique, there is little if any trouble with them.

The question whether the operation should be done or not, depends chiefly upon the results. The vast majority of fractures and dislocatlons of the spine are certainly incurable without operation. For example, Gurlt records two hundred and seventeen deaths out of a total of two hundred and seventy fracturcs, and in many of the fifty-three who recovered life was scarcely worth the living.

On the other hand, the cases already quoted, in which even the absence of knee-jerk seemed to show a total transverse lesion of the cord, but which nevertheless recovered after operation, show that much is to be accomplished in a few cases. The remarkable improvement in the bed-sores, which not uncommonly are arrested in their ravages after operation, would alone make the operation sometimes advisable, and the improvement in the urine sometimes noticed would also be encouragement in the same direction. In addition to this, Thorburn has collected sixty-one cases in which an operation was done. Only thirty-five (fifty-seven per cent.) died. In Gurlt's two hundred and seventy cases not operated on, eighty per cent. died. The mortality after operation, therefore, is much less than when no operation has been done.

For the present, then, until a larger experience has given us grounds for a more precise conclusion, it would seem proper to give patients suffering from such almost hopeless injuries the small but reasonable chance which an operation affords, and that the operation should be done at an early rather than at a late period.

VIII. Fixation by Silk or Wire.—In a former brief paper on the "Surgery of the Spinal Cord" (Reference Handbook, Vol. VIII., p. 492), I have already referred to Wilkins' case, in which he fixed the two adjacent vertebræ between which a hernia occurred, by a figure-of-eight sterilized silk ligature passed through the intervertebral notches. Since that time Hadra, of Galveston, Tex. (*Phila. Medical Times and Register*, May 23, 1891), has proposed to wire the spinous processes of the vertebræ together as a means of immobilizing them in fracture and in Pott's disease. Hadra's patient was one who had a fracture of the sixth cervical vertebra, which was dislocated forward and rotated on its vertical axis to the right. At a later time, when bending his neck too much, he was paralyzed, his head and neck being turned to the right; his right hand numb; right arm weak; girdle pains around the upper abdomen; bladder not fully under control; slight priapism. Crepitus was observed ten months after the accident. At the operation the vertebral canal was not opened, but the sixth and seventh spines were wired together by silver wire in figure-of-eight. After some weeks, thinking the wire had become loose, it was removed and a new one put in its place. This patient I saw in the winter of 1891 and 1892. He was perfectly free from any paralysis, but the inability to move his head well, and especially to do without some support, was still quite marked, and disabled him, practically, from any form of labor.

IX. Tumors of the Spinal Cord.—In the Reference Handbook, Vol. VI., p. 89, Dr. Zenner has given an admirable résumé of the chief phenomena connected with spinal tumors. A few points, however, that have been developed since his paper was written, may be of value.

Operative interference was undertaken only in one case prior to 1887. This is reported by Johnson ("Trans. Path. Soc. of London," xviii., 16). It was a congenital lipoma of the sacral region, extending to the cord. Recovery ensued after the operation, with great relief of the symptoms, but the patient (eleven months of age), died six weeks later from acute peritonitis. Practically this was an isolated case and invited no repetition until the brilliant paper of Gowers and Horsley ("Medico-Chirurgical Transactions," 1888, vol. lxxi.) appeared. In this paper Horsley has pointed out that, excluding parasites, such tumors are chiefly of the connective-tissue type. Even the intra-dural tumors are generally covered by a thin capsule derived from the pia and arachnoid, and can be easily removed without damage to the cord. In the initial stage they are ofteu mistaken for rheumatism, especially on account of the pain, which resembles rheumatic pain not a little. But the march of the symptoms is very different from that seen in rheumatism. In spinal tumors the pain is followed by muscular paralysis, and later by sensory paralysis. In a few cases Brown-Séquard's paralysis has been observed. In this, from the crossing of the sensory and motor nerves at different levels, there will be anæsthesia on the opposite side from the tumor, with hyperæsthesia, ataxia, paralysis, and exaggerated reflexes on the same side. If carefully observed this difference of the symptoms on the opposite sides of the body will enable us to localize the tumor very much more exactly than otherwise. The pain is almost always referred to a lower level than the lesion, on account of the intra-spinal course of the nerve-roots (Fig. 587), and especially on account of the as yet undetermined course of the nerve-roots after they enter the spinal cord.

Hence, if we localize the tumor by the area of pain we are very apt to locate it below its real level. In Gowers' and Horsley's case, the tumor was opposite the third dorsal body, but was referred to the fifth root, and lay at a level four inches above the zone of anæsthesia. This difference in the level of the pain and anæsthesia on the one hand, and of the tumor on the other, was within an ace of causing absolute failure in this, the most remarkable case of spinal surgery on record; for when Horsley had removed the laminæ of the third, fourth, fifth, sixth, and seventh dorsal vertebræ, nothing pathological was discovered, and it was only after removal of the lamina of the second dorsal that the tumor was discovered.

Horsley calls attention to the fact that it is necessary to define with the greatest possible accuracy the upper border of the hyperæsthetic or paræsthetic zone above the level of the anæsthesia, and that when the spine is operated on it should be explored to the very *highest* point suggested by any definite symptoms, including even *slight* paræsthesia.

Again, it is to be noted also that the favorite position of tumors is below the middle of the cervical region, and at the upper and lower ends of the dorsal region. They occasionally, however, appear in the cauda equina and other parts of the spine. In the dorsal region the tumor is, as a rule, situated higher than the point of tenderness, but not in the cervical. Stiffness and weakness of the spinal column correspond pretty closely with the position of the tumor. If the spine be curved to one side the cavity is on the same side as the growth, as a rule. Spastic

rigidity is marked in at least half the cases of intra-dural tumors; in extra-dural in but a small proportion. The reflexes are first markedly exaggerated, and then as the tumor slowly progresses they are gradually lost from below upward. Spasms occur in about sixty-one per cent. of the intra-dural and thirty-five per cent. of the extra-dural tumors. Most of the cases cover two years or more, and the paralyses of both motion and sensation are not sudden as is usual in cerebral tumors, but increase slowly. Pressure lesions in the cauda equina progress even more slowly than in the cord.

Horsley tabulates fifty-eight cases, of which only two received any benefit from treatment, and eighty per cent. died as a direct result of the tumors. All, he thinks, might have been relieved by surgical interfereuce, and probably a number even cured. In 1882 Bramwell was the first one to suggest the removal of extra-medullary tumors, and in 1887 Gowers suggested, and Horsley executed, the first really modern operation for such a removal. The man was forty-two years of age, and the tumor apparently arose from a sprain. In June, 1884, the pain was first noticed. It varied very much for two years, sometimes almost ceasing, at other times the patient was scarcely able to walk, and his irritability was such that even his sanity was questioned. Early in 1887 his legs became paretic, first the left leg, and a few weeks afterward the right, until he was completely paralyzed; sensation was impaired, and retention of urine occurred. There was anæsthesia as high as the area of skin supplied by the fifth dorsal nerve, with doubtful diminution of sensibility in the area supplied by the fourth. In the region supplied by the fifth and seventh intercostal nerves there was severe pain, much more marked on the left side than on the right, and increased to agony on any movement. The urine was purulent. Mr. Horsley, as already stated, removed the tumor with the gratifying result that in seven months the patient could walk three miles with ease, and in a year was able to do a day's work of sixteen hours, including much standing and walking about, and was entirely free from pain and discomfort.

Wright (Thorburn, "Surg. of the Spinal Cord," p. 168) has operated on a case of fibro-sarcoma of the neck, involving the brachial plexus, which invaded the cord through the intervertebral foramen for the third cervical nerve. The tumor, which was a fibro-myxoma about the size and shape of a lemon and encapsulated, was removed by an ordinary dissection. A Volkmann's spoon was then introduced into the intervertebral foramen and the growth scraped away. Recovery of the patient followed, and also immediate relief of the symptoms.

Rehn (*Archiv f. klin. Chir.*, 1891, xlii., 812) has reported a case (observed by Laquer and operated on by Rehn) of lymphangioma cavernosum, compressing the cauda equina, the removal of which was followed by recovery and relief. The patient was a young man of nineteen, who first noticed his pain in the sacral region and in the back of the thigh in September, 1888. At first this was the only symptom present, but in two years there was paralysis of the bladder and the rectum, loss of patellar reflex on the right side and weakening of it on the left, no ataxia, no disturbance of sensibility, and no atrophy of the muscles. The patient walked with a stiff leg and in a slightly stooping posture. He became exhausted after a few steps, and could only obtain sleep by narcotics. He lay in bed on his right side with the lumbo-sacral region pushed markedly backward. Every motion caused him great pain. There was, however, no decided paralysis. A tumor was suspected both by Laquer and Rehn, who operated October 14, 1890. He chiselled upward from the lower end of the sacrum, and at the upper border of the second sacral vertebra came upon a small tumor as thick as the finger, with a blue, translucent capsule. The tumor was removed partly with the scissors and forceps, and partly with a sharp spoon. The dura mater and the nerves were pushed toward the anterior wall of the canal. The patient made a good recovery and was dismissed in a month. His pain was gone, the patellar reflexes were restored, and he was able to walk without difficulty and to resume light labor.

Abbe (New York *Medical Record*, July 26, 1890) has also reported two cases of tumor of the spinal cord upon which he has operated. The first was a man aged twenty-two, who was taken with pain in the back in January, 1888. During March his sense of touch was dulled in the legs and the muscular power weakened, and a line of hyperæsthesia formed about the waist. Incontinence of urine and fæces followed, and the tumor grew so rapidly that by May 26, 1888, it seemed that he would soon die. Abbe removed the arches of the eighth, ninth, and tenth dorsal vertebræ. Outside the arches of the ninth, which were carious, and also filling up the intervertebral canal, was a quantity of inspissated pus and a tubercular neoplasm 2.5 inches long. Thorough curetting was performed, and a plaster jacket was applied. On the eighth day sensation began to return, in three weeks he could move his legs and toes, pain disappeared in three months, and he walked with crutches in eight months, being then robust and hearty. Two years later, after having remained in good health, an abscess formed in the cicatrix and the sinus which led down to the bone was curetted. The other case was that of a man forty-two years of age, who suffered from an extra-dural sarcoma. He was injured in 1887; six months later, when lifting a piano, he experienced an excruciating pain in the back. July 1, 1889, his spine was jarred severely by alighting violently on his feet, and a week later this accident again occurred. In two weeks he found it painful to rise. At the end of five weeks paresis of the legs set in; paraplegia and anæsthesia were complete by August 23d. The paraplegia was diagnosticated to arise from pressure, and it was hoped that it was from Pott's disease. His urine soon afterward showed albumin, and this was followed by chills, sweating, and vomiting, with a deep ulceration of the rectum. On April 16, 1890, Abbe operated, removing the arches of the eighth, ninth, and tenth vertebræ, and found a sarcoma filling the vertebral canal and compressing the cord to half its normal bulk. On the fifth day the patient began hiccoughing and vomiting, and finally died on the ninth day from exhaustion.

Deaver (*Amer. Journ. of the Med. Sci.*, December, 1888, p. 564) operated upon a patient of Lloyd's, who was thought to have a tumor of the cervical spine. There were paresis of the left arm, paralysis of the left leg, and exaggerated reflexes, but neither paræsthesia nor anæsthesia. He removed the laminæ of the third and fourth cervical vertebræ, but found nothing abnormal in the cord or membranes. Puncture of the cord with a needle produced exceedingly irregular respiration, which continued until her death, three days later. The post-mortem examination showed no tumor, but an old extravasation of blood and degeneration of the cord.

Dereum and White (*Annals of Surgery*, vol. ix., p. 424, 1889) have reported also one case of paraplegia thought to be due possibly to a tumor. No tumor was found, but the removal of the connective tissue outside the dura and separation of subdural adhesions were followed by marked improvement in sensation, which was still progressing when the case was reported.

X. Syringo-myelia.—So far as I know, Abbe's is the only case of this form of glioma of the spinal cord that has been operated on and reported (*Journal of Nerv. and Ment. Dis.*, July, 1892, 512). He removed the ninth, tenth, and eleventh dorsal laminæ, and found a fusiform dilatation of the spinal cord, with no pulsation; and on slitting up the dura no cerebro-spinal fluid escaped. By touch a lemon-shaped, central cyst was discovered and aspirated by a hypodermatic syringe. The withdrawal of 3 jss. of fluid was followed by collapse of the cyst. The patient recovered from the operation and showed some improvement, but died seven months later from cystitis and other complications. I have myself done two operations on similar cases, which have not as yet been reported. In one of them, done January 31, 1891, at the Philadelphia Orthopædic Hospital and Infirmary for Nervous Diseases, I exposed the lower cervical and upper dorsal cord, and found what I and the experienced neurologists present all supposed to be a very thin,

grayish-white layer of lymph on the surface of the cord, under which was a dark, blackish-gray tumor, which I thought lay posterior to the cord. In a few minutes my suspicions were aroused that I was wrong, and I discovered that the excessively thin layer of supposed lymph was the thinned layer of the white matter of the cord, and that the mass which I took for a tumor back of the cord was really a glioma of the cord itself. I, of course, instantly desisted from operation and closed the wound. The patient lived five days, and the post-mortem revealed a very extensive syringomyelia.

The second case I have every reason to believe was a syringo-myelia, from appearances, but happily I have not yet had the opportunity of making a post-mortem. The operation was done on a patient of Drs. Putnam and Warren, of Boston, on December 28, 1891. In that case I removed the arches of the tenth, eleventh, and twelfth dorsal vertebræ. The cord was greatly thickened, of a dark-gray color, and was adherent to the dura. No cerebro-spinal fluid escaped on slitting up the membranes, which I did not suture, but left open for about two inches in order to relieve the pressure on the cord. No trouble has arisen from any adhesion between the cord and the adjacent soft parts. The patient has shown a little improvement. There was evidently no localized cyst, but probably an extensive syringo-myelia.

These, so far as I know, are the only three cases that have been operated on. These results show that where the diagnosis of syringo-myelia can be made beforehand —a difficult task in many cases—it would be best to abstain from operation.

XI. Technique of Laminectomy.—Before any operation on the spine, the usual cleansing and, if need be, shaving of the back should be done over a very large area. The preparation of the surgeon's hands, instruments, etc., differs in no way from that which prevails in an ordinary operation. He should be provided with about two dozen hæmostatic forceps and with various rongeur and bone forceps, raspatories, etc. The patient is placed on his abdomen, and thus the anæsthetic must be administered in a most unfavorable position, the face being at the edge of the table; and if the injury is high up, the muscles of the abdomen and chest being paralyzed, the conditions are still more unfavorable. Great care, therefore, should be used in administering the anæsthetic, and this responsible post should be filled only by one who has had large experience, and whose judgment can be relied upon. Strychnia, digitalis, and atropia should be ready to be administered if the necessities of the case call for them, and the patient should be well protected from chilling, both by blankets covering all the body except the field of operation, and by hot-water bottles.

An incision is made in the middle line, not less than four inches long, even for a single lamina, and as much longer as is necessary. Other incisions have been proposed, such as the "T" and "V" incisions, as well as the "H" by Bullard and Burrell, the last with a view of lifting the posterior arches with the muscles and replacing them later. Ample experience has proved, however, that the longitudinal incision is quite sufficient. If there be any difficulty in separating the edges widely enough, which I have never found to be the case, an incision may be made in the fascia at right angles to the first. Next the muscles are to be cut away from the arches, which must be laid bare so as to be clearly seen. It is much better to cut the muscles away from the arches so far as it can be done instead of doing any blunt dissection, in order that there shall be as few ragged fragments of muscular tissue as possible which may undergo necrosis, with probable later suppuration. When the muscles have been cut away a raspatory can then be used to remove entirely the fragments of muscle adhering to the arches, and so expose them clearly to sight. During this dissection the hæmorrhage will be very free, and the technique of Horsley is the best, viz., the moment that one side has been cleared, pack it thoroughly with sponges wrung out of hot water, and then proceed with the opposite side. By the time the other side has been cleared the sponges can be removed from the first, and a clean field is thus secured.

To remove the arches the interspinal ligaments should first be cut by a vertical incision, and some care should be taken that the knife does not enter the spinal canal and wound the membranes and the cord during this step. This is an especial danger only in the cervical or lumbar region, as in the dorsal the laminæ overlap so much that this danger is *nil*. Hey's saw, the trephine, and the variously-shaped cutting forceps have been used to open the canal. Abbe (New York *Medical Record*, July 26, 1890) has proposed not to remove the arches entirely, but after separating the muscles on one side to cut loose the spines at their bases, leaving them attached to the other lateral flap instead of to the upper and lower flap in the "H" incision proposed by Bullard and Burrell. I can scarcely see any especial advantage in either of these procedures, and a possible disadvantage of wounding the cord by spiculæ of the replaced bone. The fear that has been expressed by Pilcher and others, that the solidity of the spinal column would be impaired by removal of the arches has not been realized. The bodies of the vertebræ carry the superincumbent weight, and the arches are practically merely to complete the canal for protection of the cord.

During this removal of the arches in the cervical region care must be taken not to wound the vertebral artery.

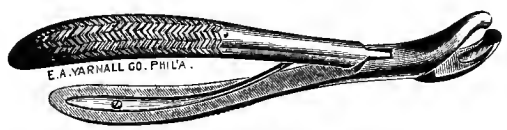


Fig. 590.—Double Rongeur Forceps.

This caution would seem almost superfluous were it not for the fact that Chipault (*Rev. de Chir.*, August, 1892, 685) states that in at least three cases speedy death has resulted from wounding this vessel. He gives, however, no references to the cases, and I have not found any such reported. The best and quickest method of opening the spinal cord I have found is to gnaw away the spinous processes, and then a part of one of the arches by the double rongeur forceps (Fig. 590), and then the arches can be bitten away to any extent by the rongeur forceps which I devised originally for linear craniotomy, but which answers this purpose admirably (Fig. 591). Occasionally there will be considerable hæmorrhage from the vessels, especially the veins within the spinal canal. This can usually be controlled very soon by pressure and hot water.

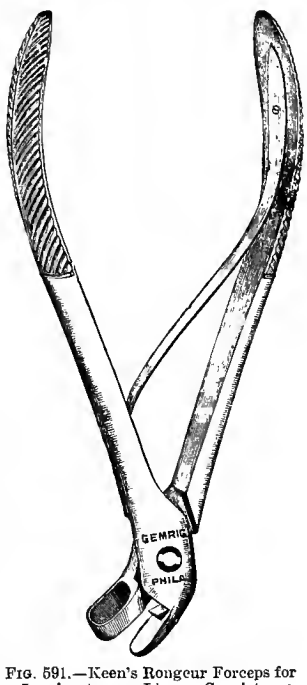

Fig. 591.—Keen's Rongeur Forceps for Laminectomy, Linear Craniotomy, etc.

Between the membrane and the bones is usually a moderately thick layer of fatty tissue which can be best treated by dividing it in the middle line, and pushing it to each side with small bits of gauze or sponge. As soon as it is pushed aside it gives no further trouble. The dura should next be observed as to whether it pulsates, for if not, there are probably either some adhesions or other

causes of interference in the continuity of the subdural space. The color may indicate whether there is blood or pus underneath the dura, and its tension will show whether there is more cerebro-spinal fluid within the membrane than there ought to be.

Touch will also verify this. But although there may be no excess of cerebro-spinal fluid, there may be thickening of the cord from a tumor, or syringo-myelia, etc., or thickening of the dura itself, all of which can be more or less well appreciated by touch. If it be necessary to examine the bodies of the vertebræ, the cord and its membranes can be carefully drawn to one side by means of an aneurism needle or other similar instrument, so as to expose the bodies of the vertebræ both for observation and, if need be, for operation. Mills has proposed to cut one or two nerve-roots if necessary, but this, as a rule, does not seem to be needful. To facilitate such observation Chipault places two cushions under the patient, so that the spine will be concave backward, which will facilitate the lifting of the cord. The nerves are sufficiently elastic to allow of moderate stretching. At this stage any extra-dural tumor, thickening of the dura on its external surface, or any further pressure by dislocation or fracture of the arches or bodies of the vertebræ can be suitably treated.

The question of opening the dura is a somewhat more serious one in the spine than in the brain. In the brain we can close the opening without drainage and prevent the continuous escape of the cerebro-spinal fluid. In the spine this is not so easily done, as the injury to the thick muscles sometimes prevents absolute primary union, and so favors the establishment of a fistula. Such a fistula is not only a source of irritation to the surrounding skin, and an annoyance by its constant dressing, but also, as has been observed by Verneuil and Chipault, subsequent infection may take place through such a sinus. The mere escape of the cerebro-spinal fluid itself is not a very serious matter. On p. 814 a case of withdrawal of very large quantities of cerebro-spinal fluid shows how innocuous this is, and in many cases of spinal operation the escape has been free and continuous for some time. As a rule, however, in the spine as in the brain, in spite of these objections, it is best to open the dura, and, when the operation is completed to suture it with a continuous catgut suture so as to favor speedy union. If it is not opened serious errors may occur, due to defective information about the cord. Once that it is opened, the condition of the subdural space can be ascertained by the dural separator of Horsley or by an ordinary bent probe, and it should certainly be explored both upward and downward. The same is true of the space between the dura and the laminæ. This should be explored to determine any irregularities, obstructions, etc. If there be a tumor of the cord, if it be on the surface of the cord, it can now be removed, usually with ease. If it involve the substance of the cord it is more difficult of treatment, and may require such serious injury of the cord as may make it inadvisable to remove it. If the cord has been injured or crushed by accident, little can be done beyond freeing it from pressure. It has been proposed to suture the cord by Morris (*Annals of Surgery*, 1886, iii., 490), Abbe (*Medical Record*, July 26, 1889, 85), Maydl, and others, but no successful case has been reported. Duncan (*Edinburgh Medical Journal*, March, 1889, 883) has stitched the sheath above and below, but this attempt also failed. Leckie (*British Medical Journal*, October 1, 1892) has even proposed to shorten the spine by removing the part or whole of a vertebra, or portions of two adjacent vertebræ if necessary, by means of gouges or drills; a proposal which will scarcely meet with any favor. In gunshot wound of the cord, Tuffier has sutured the nerves themselves.

Occasionally, after opening the theca and instituting suitable treatment of the cord, it will be better to leave the dura open. In one case of my own, probably a syringo-myelia, in order to relieve the pressure on the cord I left the dura open for a space of two inches; and Horsley has left it open for as much as four inches. Two dangers exist in connection with this. First, the continuous escape of cerebro-spinal fluid, already alluded to, and secondly, possible injurious effects from cicatricial adhesion of the soft parts to the posterior surface of the cord. As yet, however, in reported cases there does not seem to have been any pain or other unfavorable symptom as a result of such adhesions. As a rule, it is much better to suture the dura, and in such a manner that the two internal or serous surfaces shall be in approximation, in order to obtain the speediest union. This may be done either by continuous or by interrupted sutures of catgut or fine silk. I have found the best means of applying the suture to be with the finest semicircular Hagedorn needle and a needle-holder. In order that the dura may close and prevent the continuous escape of the fluid, no drain should be inserted under it. It is much better, however, to place a rubber drainage-tube for a day or two, deep under the muscles, on account of the free oozing which will always follow so extensive a wound. The muscles should be approximated by buried sutures of catgut, the skin being sutured in the ordinary way, and the usual antiseptic or aseptic dressings applied.

After-treatment. — The first redressing will usually have to be made within the first twenty-four hours, or possibly twice during the first day, on account of the free oozing and the escape of cerebro-spinal fluid. The most careful antiseptic precautions should be observed in the redressing, lest infection should take place. The drainage-tube may be removed usually in twenty-four to thirty-six hours. Especial care should be taken, that if there are bed-sores present no contamination occur through them, and also, if control of the bladder and bowels has been lost, that infection do not arise from these sources. Thorburn has proposed to drain the bladder by a suprapubic cystotomy after injury of the cord, passing by this means through parts which are not anæsthetic or apt to slough, and preventing the constant wetting of the wound as a result of the incontinence of urine; an operation which would seem to be reasonable, although I am not aware of its having been done. The bed-sores will often improve very much, and even get well, after such an operation. The ordinary care as to food, etc., will suggest itself to every operator. *W. W. Keen.*

STOMACH DIGESTION AND THE TESTS OF ITS EFFICIENCY EMPLOYED IN DIAGNOSIS. The careful study of the past few years into the physiology of gastric digestion, and the desire on the part of clinicians to apply the knowledge thus gained to the more accurate differentiation of the various disorders of the stomach, have developed methods of examination for diagnostic purposes requiring special description. Before considering these in detail, it will be well to briefly summarize our present knowledge of the digestive process within the stomach.

Gastric digestion may be divided into two periods of unequal duration, a first or amylolytic period, and a second or proteolytic period. The amylolytic period usually lasts for about three-quarters of an hour after the ingestion of an ordinary meal. During its continuance the reaction of the gastric contents is alkaline, the acidity of the gastric juice secreted at the beginning of gastric digestion being neutralized by the alkaline food and saliva, and the amylolytic action of the saliva continues. Starches are converted through the activity of the ptyalin into achroödextrin, erythrodextrin, and in part into glucose, and saccharose is in great part split up into glucose. These changes take place rapidly and soon cease, but they are usually soon followed by a fermentative change of a different nature, dependent upon the presence of ordinary germs of fermentation in the ingested food. These in their growth split up a certain amount of the glucose resulting from the amylolytic action of the saliva, with the resultant formation of lactic acid. As this fermentation can go on only in a feebly alkaline or neutral medium, it is quickly terminated by the appearance of free hydrochloric acid.

Although the secretion of gastric juice is at once stimulated by the entrance of food into the stomach, the

time at which free hydrochloric acid appears in the stomach contents varies greatly with the nature of the food taken. Thus, food rich in alkalies and proteids, by chemically combining with the acid of the gastric juice, materially delays the appearance of free acid in the stomach. With the appearance of free acid the amylolytic period comes to an end, the amylolytic action of ptyalin being thereby interfered with, and the proteolytic period begins.

This period is characterized chiefly by the conversion of the proteids of the food into albumoses and peptones through the agency of the pepsin of the gastric juice. This latter is secreted by the gastric mucous membrane in the form of propepsin, an inert substance which becomes changed into the active ferment in the presence of free hydrochloric acid. Though secreted during the amylolytic period, its proteolytic action is therefore delayed until the presence of free acid brings the first period to an end and inaugurates the second. Through the same agency the lactic acid and other mycotic fermentations which may have been active during the amylolytic period are arrested, an acid medium preventing the development of the necessary germs, and shortly after the commencement of the proteolytic period the organic acids formed as the result of these fermentations disappear.

Since the secretion of gastric juice continues so long as there is food remaining in the stomach, a continual increase in the acidity of the gastric contents would be expected after the first appearance of free hydrochloric acid. This is, however, not the case, as much of the free acid after a time becomes loosely combined with the products of the digestion of the proteids of the food, with the albumoses, peptones, leucin, tyrosin, etc. This fact is of great importance, as the hydrochloric acid so combined is powerless as a digestive agent; and it not infrequently happens that the proteolytic action of the gastric juice is in this way materially impaired. Furthermore, the low content of free hydrochloric acid in the stomach contents at this time may cause the physician to underestimate the secretory activity of the gastric mucous membrane, and may lead him into error of diagnosis in that way. It is accordingly only after the stomach has in a measure emptied itself of the products of proteid digestion, that the maximum content (0.2 per cent.) of free hydrochloric acid is reached. The time at which this occurs differs with the character of the food, the presence of a considerable quantity of albuminous material markedly delaying it, so that after a meal rich in proteids the maximum acidity of the gastric contents is not reached till four hours or more after the ingestion of the food, though reached in about two hours after a meal composed chiefly of carbohydrates.

Besides propepsin and hydrochloric acid, the gastric mucous membrane elaborates lab-zymogen, an inert substance converted by free hydrochloric acid into the active lab-ferment, causing the coagulation of the casein of milk. As the conditions modifying the secretion of this substance are at present little understood, and it is consequently of small diagnostic significance, it may be passed without further notice.

During the entire period of stomach digestion energetic peristalsis materially aids in the mixing of the digestive juices with the food, and as the latter becomes more and more liquid, is an active factor in its discharge into the duodenum. At the expiration of six hours after the ingestion of an ordinary meal the stomach should be empty. Until the next meal it should remain more or less quiescent and should contain only a small amount of thin liquid of neutral reaction, and containing neither pepsin nor hydrochloric acid.

It is probable that very little absorption is accomplished by the gastric mucous membrane. The more liquid portions of the food are quickly driven into the duodenum as the result of the peristaltic activity of the stomach, and the products of ordinary proteid digestion in the stomach, the albumoses and peptones, are now known to be less readily assimilable than was formerly supposed. It is fair, therefore, other things being equal, to judge of the muscular activity of the gastric wall from the time elapsing after the ingestion of a meal and until the stomach has completely emptied itself.

With these fundamental facts of normal gastric digestion in mind, the particular effect upon digestion of any given departure from the normal of either the secretory or motor function of the stomach may be readily inferred.

Diminished secretion of hydrochloric acid* permits undue prolongation of the amylolytic period and continuance of the mycotic fermentative processes, which normally occur during that period, and causes delay in proteid digestion. The fermentative processes lead to the formation of lactic and other organic acids as well as to the production of an excessive amount of gas. These lower the tone of the stomach and interfere materially with its normal peristalsis, thus augmenting the injurious effect of delayed proteid digestion with its resultant stagnation of food in the stomach. This condition of insufficient hydrochloric-acid secretion is made evident by the discovery of a low percentage or absence, so far as our tests indicate, of free hydrochloric acid in the stomach contents throughout the whole course of digestion; by the presence of fermentative products, especially lactic acid, in excess or at a time when they should have disappeared; by the delayed emptying of the stomach; by the presence of undigested proteids in the stomach contents seven hours or so after the ingestion of the meal; and by the fact that the digestive power of the gastric juice, tested experimentally, is below the normal.

Excessive hydrochloric-acid secretion shortens the amylolytic period, and so interferes with the digestion of the amyloids of the food. If associated with proportionate increase in the secretion of propepsin, it may hasten digestion unduly and out of proportion to the ability of the stomach to empty itself. Usually, however, excessive hydrochloric-acid secretion is not accompanied by proportionate secretion of propepsin, and the excessive acidity tends rather to delay than to accelerate digestion. In either case there is usually more or less stagnation of the gastric contents, which, being more irritative than usual, in time lead to inflammatory changes in the gastric mucous membrane, with resultant diminution of acid secretion. Hyperacidity is indicated by an increased percentage of free hydrochloric acid throughout gastric digestion and by its earlier appearance; by the finding in the gastric contents of remains of undigested starches, the amylolytic period having been shortened; by the shortening of the time of gastric digestion in many cases, though not in all; and experimental testing of the digestive power of the gastric juice may show it to be abnormally active.

We have seen that inefficient motor activity of the gastric wall may be a result of either diminished or excessive secretion, and that it then intensifies the primary abnormal condition. But it may also result from mechanical hindrance to the emptying of the stomach, notably from stenosis of the pyloric orifice. In any event it is a prime factor in the production of gastric dilatation, in which secretory disturbance, motor inactivity, and fermentation of retained materials combine to intensify the disorder already present. If, seven hours after the ingestion of an ordinary meal (better the test-meal to be presently described), the stomach is still found to contain any considerable quantity of food, we may infer diminished activity on the part of the gastric wall. The stomach contents in gastric dilatation present the following characters: decided diminution or absence of free hydrochloric acid; presence of the fatty acids of fermentation in large quantity, notably lactic, butyric, and acetic acids; low digestive power with presence in the stomach-washings of undigested fragments of all the foods ingested; and the presence of large numbers of fermentative bacteria of various kinds.

From what has been said it will be evident that the determination of the efficiency of gastric digestion in any

* The secretion of propepsin is apparently not subject to such variation as that of the hydrochloric acid, nor are slight variations in its amount of such moment. It is believed never to be absent when hydrochloric acid can be detected in the gastric contents.

given case must involve the solution of several distinct problems, each requiring its own special mode of examination. The degree of acidity of the gastric contents must be learned, as it throws important light upon the secretory activity of the stomach. The duration of ordinary stomach digestion must be determined, as it affords information not only as to the digestive power of the gastric juice, but as to the motor activity of the stomach itself. The content of lactic acid must be studied, as its presence in excess is positive indication of abnormal fermentation. And, finally, the character of the digestive products must be investigated to determine the completeness of digestion.

The examination is usually begun by the determination of the time required for the digestion of a definite standard test-meal. Several test-meals have been proposed for this purpose, but that suggested by Leube and known by his name, is the one most commonly employed.* This consists of a plate of barley soup, six to eight ounces of well-cooked beefsteak, a French roll, and a glass of water. It should be taken on an empty stomach. Seven hours after the ingestion of this meal the stomach should be empty. At the expiration of seven hours, then, the stomach-tube should be passed and the stomach should be completely emptied of any contents, first by Ewald's expression, then by lavage.† If the stomach is found to be empty, with the exception, perhaps, of a very few shreddy remnants of the ingesta, it is proper to infer that no very material impairment of the secretory activity of the stomach is present, and that its motor function is efficiently performed. Hyperacidity or hypersecretion may, of course, exist, and in all cases in which their existence is suggested by the symptoms the test above described should be repeated, shortening the interval between the ingestion of the test-meal and the washing of the stomach until the exact time required for digestion is determined.

If, on the other hand, after an interval of seven hours the stomach is found to contain any considerable quantity of food, digestion is impaired and subsequent examination is indicated to determine the precise character of the defect. Again, if the period of gastric digestion is markedly shortened, further examination will be necessary to learn whether this is the result of hypersecretion or of excessive motor activity, such as is occasionally met with in certain forms of nervous hyperexcitability.

The great value of this test as a preliminary, directing the course of subsequent examination, must be apparent.

The existence, then, of abnormality of gastric digestion having been shown by the test above described, we pass to subsequent tests directed to the determination of the following points :

1. Is the food properly disintegrated and mixed with the gastric juice, and does it contain extraneous substances, as blood, bile, pus, bacteria, etc., whose presence may throw light upon the existence of organic disease of the stomach ?

2. Is it acid, and, if so, is free hydrochloric acid present ?

3. Are lactic acid and other products of fermentation in excess of the normal ?

4. What is the total acidity, and what the quantity of free hydrochloric acid present ?

5. What is the digestive power of the gastric secretion as indicated by the amount of peptone present in the stomach contents, and by the artificial digestive power of the filtered gastric juice ?

6. What is the degree of motor activity of the gastric wall ?

These we shall consider in the order given. The material obtained from the stomach in the preliminary test may be employed for this subsequent examination, or the stomach may be emptied again four or five hours after the ingestion of another test-meal.

1. Careful inspection of the gastric contents frequently throws much light upon the disorder of digestion. The food may have been imperfectly masticated and may appear as large masses, difficult of penetration by the gastric juice and hence delaying digestion. Much mucus may be plainly visible, indicating a catarrhal condition of the mucous membrane, or blood, bile, or pus may in rare cases make their presence known to the naked eye, and may serve as valuable indications of disease of the gastric tissue.

Gross inspection should always be followed by a more minute examination with the aid of the microscope. The methods employed in this examination and the significance of the various substances occurring in stomach contents have been dwelt on in detail in treating of vomited matters in the article on Microscopy in the body of this work, and need no repetition here.

After the inspection above referred to the gastric contents obtained for examination should be thrown upon a moist filter. The filtrate is employed in the majority of the succeeding tests. The solids may be used for the microscopic examination.

2. The acidity of the filtrate is tested with litmus paper. The positive result of this test does not, however, prove the presence of hydrochloric acid, as all free acids give a similar reaction, as do also a large number of acid salts. It is necessary, therefore, to test more particularly for free hydrochloric acid.

Many tests have been proposed for this purpose, but it will be necessary to limit their description in this place to three of the most delicate, which are in most cases sufficient for all purposes of clinical examination.

(*a.*) Tropaeolin.* This is a finely crystalline brownish dye, readily soluble in alcohol, the solution having a deep amber color. This color deepens to a dark brown on addition of hydrochloric acid, and if the mixture be evaporated to dryness and gently heated, a beautiful lilac or blue color develops, the exact shade depending in part, at least, upon the quantity of acid present. This serves as an exceedingly delicate test for hydrochloric acid, yielding a positive result in solutions containing only 0.05 per cent. of hydrochloric acid alone, though less delicate in the presence of albumin, peptones, and phosphates. For the detection of free hydrochloric acid in gastric contents the test is conducted as follows :

A few drops of a saturated alcoholic solution of Tropaeolin OO are added to double the quantity of stomach filtrate in a flat porcelain dish.† If free hydrochloric

* Among other test-meals may be mentioned that of Ewald and Boas, consisting of a roll and a cup of tea, or a glass or two of water. The stomach contents should be examined one hour after ingestion of this meal. The Klemperer test-meal consists of a pint of milk and two small rolls ; and the stomach is emptied two hours after its ingestion. Both of these meals should be taken in the morning on an empty stomach. They are particularly well suited to the requirements of hospital out-practice, where the patient can be controlled for a comparatively short time only. For private practice and for ordinary hospital work, the Leube test-meal will usually be preferred.

† The passage of the stomach-tube, the various precautions, etc., to be observed in so doing, and the most approved method of washing out the stomach will be found fully described in the article, "Stomach Lavage" in this supplement. The technique of lavage there described needs no modification for diagnostic purposes. But a word is necessary regarding the method of expression recommended by Ewald. To accomplish this the tube is passed in the ordinary way, and when well in place, the patient is instructed to rather vigorously contract the muscles of the upper portion of the abdomen, as if he were vomiting. If there is anything in the stomach this is usually sufficient to force a portion of it into the tube and out at its distal end, where it should be caught in a clean dish for examination. If the muscular contractions of the patient are inefficient in forcing the stomach contents through the tube, the physician may endeavor to assist the expulsory action by pressure over the stomach during the efforts of the patient. If nothing appears at the distal extremity of the tube it must not be inferred that the stomach is necessarily empty, for a considerable amount of the stomach contents may have been forced into the lower end of the tube, or the tube may have been obstructed by large particles of undigested food. If in such a case it is particularly desired to obtain some of the gastric contents undiluted, the distal extremity of the tube should then be tightly compressed to prevent entrance of air, and to cause retention of its contents, and the tube should be removed and its contents allowed to run out into a clean dish. Whether anything has been obtained by expression or not, the stomach should be thoroughly washed out to make certain the diagnosis.

* Several dyes are manufactured in Germany under this name; that here intended is designated "Tropaeolin OO." It may be had of Merck & Co., of 71 and 73 William Street, New York.

† The writer has found the covers of the ordinary small porcelain crucibles so commonly used in chemical laboratories to be exceedingly well suited to the requirements of the color tests connected with the examination of the gastric contents. They are small, very flat, and furnish a clear white background for the color changes. They are, furthermore, so thin that the heat necessary to most of the tests may be got from a single match burning under them.

acid is present in any considerable quantity the color of the tropaeolin solution will deepen as the mixing of the two liquids takes place. But if present in only small amount no such change may be noticed, and in any case the mixture should be gently warmed, as the subsequent change in color is a much more delicate indication of the presence of free hydrochloric acid than the deepening in color above referred to. If free hydrochloric acid is present a clear beautiful lilac or blue color will develop as the mixture dries at the edges and becomes heated.

As has been said, this is an exceedingly delicate test of the presence of free hydrochloric acid. Lactic and other organic acids occurring in the gastric contents fail to give any similar reaction in any concentration in which they are found in the stomach, and their presence in no way interferes with the delicacy of the test. The presence of much albumin and of the products of proteid digestion and phosphates, somewhat impairs its delicacy, but even under these conditions the test is to be regarded as one of the most delicate at our disposal for the detection of free hydrochloric acid.

Filter-paper soaked in tropaeolin solution and afterward dried, may also be employed for this test. If hydrochloric acid is present the color should deepen on addition of a drop of the stomach filtrate, and the lilac color should develop as before on gently heating to dryness. The test is, however, considerably less delicate when conducted in this way, and, if negative, should never be accepted as final unless corroborated.

It should be remembered that the delicate and characteristic part of this test is the development of the lilac color, and that this may often appear on heating when there has been no perceptible deepening of the color on mixing the two solutions. The heating should, therefore, never be neglected.

(*b.*) Phloroglucin-Vanillin Test (Günzburg's Test). This is by far the most delicate and reliable test which has been proposed for the detection of free hydrochloric acid in the gastric contents. It depends on the development of a characteristic red color in an otherwise colorless solution.

The reagent proposed by Günzburg and known by his name, has the following composition:

Phloroglucin	2 grm.
Vanillin	1 grm.
Absolute alcohol	30 c.c.

It should be kept in a dark blue or brown bottle, as it is less stable in the light. The test is conducted precisely like the tropaeolin test. A few drops of the stomach filtrate are mixed with an equal amount of the reagent in a flat porcelain dish, and the mixture is *gently* heated. If free hydrochloric acid is present a brilliant carmine-red mirror develops as the mixture dries and becomes heated. This color should remain unchanged after treatment with ether. If free hydrochloric acid is not present a yellowish-brown residue is left after evaporation.

Organic acids yield no similar reaction in any concentration, and their presence in the solutions tested in no way interferes with the delicacy of the reaction. The test is further valuable in that it responds in the presence of *free* hydrochloric acid only, that which is loosely combined with the albuminoids of the food, etc., and is consequently useless for purposes of digestion, not giving the characteristic reaction. It, therefore, gives information as to the existence in the gastric contents of hydrochloric acid in the condition necessary for digestion.

The formula given above is that originally proposed by Günzburg. Boas has recently proposed a slight modification of it, claiming greater stability and somewhat greater delicacy for the modified reagent. His formula is as follows:

Phloroglucin	2 grm.
Vanillin	1 grm.
Alcohol (eighty per cent.)	100 c.c.

This is employed in the same way as the original Günzburg reagent, and the result is the same.

Phloroglucin-vanillin paper may be prepared by soaking washed filter-paper in the reagent and drying it. This, also, should be kept in a dark bottle. It is used precisely as the tropaeolin paper.

(*c.*) Resorcin Test (Boas). This test is said by its inventor to be as delicate as the phloroglucin-vanillin test. The reaction is similar.

The reagent employed has the following formula:

Resorcin resublimat.	5 grm.
Sacchar. alb.	3 grm.
Spiritus dil.	100 c.c.

Five or six drops of stomach filtrate are mixed with from three to five drops of the reagent in a white porcelain dish, and are gently evaporated to dryness, when a fine rose or cinnabar color is produced, which disappears on cooling.

Organic acids are said to give no similar reaction.

3. Having been informed by the above-described tests as to the presence or absence of free hydrochloric acid in the stomach contents under examination, we proceed to the third step in our analysis, the determination of the presence of organic acids. As lactic acid is by far the most constant of these under those conditions which lead to their formation, and as its determination is both simpler and more delicate, we shall limit our description to a consideration of its principal test, alluding only cursorily to the reaction of butyric and acetic acids.

The most delicate reaction for lactic acid is that proposed by Uffelmann. The reagent employed consists of

Carbolic acid (two per cent.)	100 c.c.
Liq. ferri chloridi	1 to 2 drops.

This reagent has a steel-blue color. Its ingredients should be kept in separate bottles and should be mixed immediately before applying the test, as it quickly changes and becomes useless for the detection of lactic acid. Under the action of lactic acid this solution is quickly decolorized and a greenish-yellow coloration develops. Hydrochloric acid simply decolorizes the reagent. Butyric and acetic acids cause an orange-yellow coloration; they rarely lead to much confusion, owing to their characteristic odors. But a reaction very similar to that caused by lactic acid is caused by alcohol, sugar, and various acid salts, though the green quality of the final color is less distinct.

In making use of this test for the detection of lactic acid in the stomach contents, a few cubic centimetres of the freshly prepared reagent are poured out into a flat porcelain evaporating-dish or a test-tube and the stomach filtrate is slowly added, when, if lactic acid is present in any significant amount the characteristic greenish-yellow color will appear. If the previous test for hydrochloric acid has shown the presence of a large quantity of it in the stomach filtrate, and on its addition the Uffelmann reagent simply becomes decolorized without the development of the characteristic color, we may infer the absence of lactic acid. If the final color produced is yellowish or orange, without the greenish tone, it should not be forgotten that the substances above named, butyric and acetic acids, alcohol, sugar, and acid salts, any of which may be present in the stomach, may cause such a reaction, and before finally admitting the presence of lactic acid a portion of the stomach filtrate should be thoroughly shaken with ether, which dissolves the organic acids, and the residue, after evaporation of the ether, should positively yield the typical lactic acid reaction.

4. The presence of free hydrochloric acid having been determined, and a rough idea of the content of organic acids having been gained by the tests already described, it becomes important to learn approximately in what quantity the hydrochloric acid may be present.

The tests which have been proposed for the exact quantitative estimation of free hydrochloric acid in the gastric contents, are all either inaccurate and therefore unsatisfactory, or necessitate complicated and tedious chemical manipulation, rendering them unsuited to the needs

of the physician. However, the estimation of the total acidity is easy, and in cases in which the result of Uffelmann's reaction has been negative, and we may fairly exclude the presence of organic acids in any material amount, the result of the determination of the total acidity affords sufficiently accurate data for most diagnostic purposes. It alone will be described here, the reader being referred to more special works for descriptions of the more complex methods of analysis. (*Von Jaksch, Boas, Leo.*)

The estimation of the total acidity is accomplished by titration of a measured quantity of the stomach filtrate with a standard solution of alkali. The standard alkaline solution is made by dissolving four grammes of sodium hydrate (5.6 grammes of potassium hydrate) in a litre of distilled water. One cubic centimetre of this solution should exactly neutralize 0.00365 grammes of hydrochloric acid. It is slowly dropped from a graduated burette into a carefully measured quantity of the stomach filtrate to which a small quantity of an aqueous solution of Congo red has been added. In the presence of acid Congo red changes to a deep blue, and the titration is therefore continued until the reappearance of the characteristic brilliant red color of the Congo red in neutral and alkaline solutions. The instant at which this occurs marks the complete saturation of all the acid combinable with the alkali employed. By reading off on the burette the number of cubic centimetres of the alkaline solution required to accomplish this neutralization, by multiplying this number by 0.00365, the amount of hydrochloric acid equivalent to one cubic centimetre of the alkaline solution, and by then dividing by the number of cubic centimetres of stomach filtrate taken for the test, the content of acid in one cubic centimetre of the stomach filtrate is determined, and from this the percentage may readily be calculated by multiplying by one hundred. Thus, if 6 c.c. of the standard alkaline solution are required to neutralize 10 c.c. of the stomach filtrate, the following formula represents the necessary calculation in determining the total acidity:

$$\frac{6 \times .00365 \times 100}{10} = .219 \text{ per cent.}$$

It will have been observed that in this estimation the acidity is calculated in terms of hydrochloric acid, and this at once suggests an error in the method, for we have seen that other acids may be present. Still the error is slight, as a rule, when the reaction for lactic acid has been negative. Of far greater importance, however, is the fact that by this method we neutralize not only the free acids, but also that hydrochloric acid which has entered into loose chemical combination with the albuminoids of the food, the alkali used in the titration having the power to separate this combination. As this combined acid is useless for digestion, very erroneous inference as to the digestive power of the gastric juice may be drawn from the amount of total acid determined. Yet this, too, which would at first sight appear a serious error in the method, is less so when we consider that the examination is made after the ingestion of a standard test-meal, the amount of whose proteids is the same in all cases, and that accordingly the amount of hydrochloric acid entering into such combination must be always approximately the same. While, therefore, the result arrived at in the determination of the total acids fails to give information as to the amount of free acid present with that accuracy which could be desired, it still affords data for the comparison of healthy and disordered digestion sufficiently accurate for most purposes of clinical examination. It is much to be regretted that up to the present time no simple, practical, and sufficiently accurate method for the separate determination of the free and combined acid has been devised.

When the test for organic acids (Uffelmann's) has demonstrated their presence in any considerable quantity, they should be removed before the titration, by shaking with ether.

5. The digestive power of the gastric juice may be inferred from the result of two very simple tests: the first, for peptone in the stomach filtrate; the second, to determine the actual power of the stomach filtrate to digest albumin under proper conditions.

(*a*) Peptone is tested for by the ordinary "biuret reaction." A small amount of the stomach filtrate is rendered strongly alkaline by addition of sodium or potassium hydrate, and a few drops of an aqueous solution of cupric sulphate are added. If peptone is present in any considerable quantity a characteristic purple color is produced on addition of the copper salt.

In connection with this test is should be remembered that albumin, which is almost always present in some form in the gastric contents in cases of disordered digestion, gives a similar reaction, a blue-violet color, and that the distinction between these two colors may be quite difficult, leaving the physician in doubt as to whether peptone is present in large amount, indicating good digestive power on the part of the stomach, or as to a large content of albumin, indicating impaired digestive power, since at the time of the examination it should have been in great part converted into peptone.

(*b*) The most reliable test, therefore, of the digestive power of a given sample of stomach filtrate is the time which it requires for the digestion, under proper conditions, of a given quantity of albumin. Normal gastric juice should digest a piece of hard-boiled egg albumin, one centimetre square and a millimetre thick, at the body temperature, in one hour. In the test, then, such a piece of egg albumin is dropped into a test-tube, is liberally covered with stomach filtrate, and the tube is placed in a warm-air chamber or a water-bath kept at the body temperature, 37° C. If at the expiration of an hour the albumin is not digested, we may infer that the digestive power of the gastric juice is impaired.

We have seen that impairment of the digestive power of the gastric juice is almost always due to deficiency of hydrochloric acid. But occasionally, when an atrophic condition of the gastric mucous membrane exists, there may also be diminution or even abolition of the pepsin-forming function. When there is reason to suspect such a condition a second test of the digestive power of the stomach filtrate should be made, adding a few drops of dilute hydrochloric acid. If the albumin remains still undissolved after the required interval, we are justified in assuming deficiency or absence of pepsine as well as hydrochloric acid.

6. The most reliable information relative to the motor activity of the gastric wall is gained from the result of the preliminary test of the time required for the digestion of the standard test-meal, and usually the information so gained is amply sufficient for all ordinary diagnostic requirements. If, seven hours after the ingestion of the test-meal, food is still contained in the stomach, we may infer diminished motor activity on the part of the stomach.

A special test of the motor activity of the stomach has been devised by Sievers and Ewald. This test depends upon the fact that salol, which is insoluble in the stomach, is converted by the alkaline intestinal juices into phenol and salicylic acid, both of which are readily absorbed and speedily appear in the urine. In carrying out the test the patient is made to swallow with the meal a capsule containing about fifteen grains of salol. Under normal conditions salicylic acid can be detected in the urine in about an hour by the following test:

To a few drops of urine in a flat porcelain dish a drop or two of a rather dilute solution of ferric chloride is added. If salicylic acid is present a reddish-violet color is at once developed, which is permanent on standing.

If, after the ingestion of the salol capsule, this reaction does not develop in the course of an hour and a quarter, it may be inferred that the activity of the stomach is diminished, but careful tests have shown that this is not necessarily always the case. It is believed, however, that absolute absence of the reaction at any time, and after repeated testing, may be considered quite positive proof of obstruction of the pylorus.

It has been the purpose of the present article to present the principal tests of the efficiency of gastric digestion which have been developed during the past few years, and to suggest the conclusions which may be deduced from their use. Any detailed discussion of the subject is beyond the scope of this HANDBOOK, and the reader must be referred therefor to the more exhaustive works mentioned in the appended bibliography.

John Slade Ely.

STOMACH LAVAGE. Lavage of the stomach, as at present practised, consists of the introduction of a tube into the stomach, the removal of the stomach contents, and the cleansing of the gastric mucous membrane by the repeated introduction and removal of tepid water.

Though it is within a few years only that the stomach-tube has attained to anything like a widespread use in medicine, we nevertheless find that John Hunter, about the middle of the last century, made use of hollow tubes inserted into the stomach as a means of applying irritating substances to its mucous membrane. As the remedial effects of this treatment were slight the method seems to have attracted little attention. In 1822 F. Bush, an English surgeon, employed the first stomach-pump to remove the gastric contents in a case of opium poisoning. Seven years later, in 1829, the stomach-syphon was introduced by Arnott, but, though recommended by Sommerville, Blatin, and Canstatt, it was soon lost sight of, and the attention of the profession was not at all generally drawn to its use until the publications of Kussmaul in 1867 and 1869. The more recent development of the method and its general acceptance as one of the most valuable of our therapeutic resources, are due principally to the investigations of Oser, Leube, Ewald, and Boas.

The tube at first made use of was of thin rubber, and received support during its passage from a flexible stylette. This was quickly superseded by a stiff tube of cloth and gum-elastic material which could be passed without the aid of the stylette. These tubes are hard and very stiff when cold, but become moderately flexible after immersion in warm water for a few moments. They are still to be found in the shops, though their use is now almost entirely restricted to cases of profound coma, and to those in which the resistance of the patient prevents the passage of the ordinary softer tube, now commonly in use. This tube is of soft red rubber, is about twenty-eight inches long, has a calibre of about one-fourth inch, is closed at the extremity, and has two good-sized openings near its tip. This tube was originally introduced by Nélaton, and is frequently designated by his name. It is kept in stock in several sizes by all the leading instrument makers, but the size above mentioned will be found to be most generally useful.

In the selection of a stomach-tube the following points should be borne in mind. While being perfectly flexible, the tube should still have a certain amount of firmness, so that it may withstand a moderate amount of pressure without collapsing; it should be perfectly smooth everywhere, and without cracks in its surface; and the openings near its tip should have rounded edges ("velvet-edged"), so that no irritation may be caused by their sharpness. Some difference of opinion exists as to the preferable form and arrangement of these openings. Schütz and some other German observers advocate the use of a tube with an open "velvet-edged" extremity, a large elliptical opening on one side near the tip, and several small "pin-head" openings opposite this larger one. This tube is said to possess the advantages of several openings without consequent impairment of the stiffness of the tube. It has the disadvantage common to all tubes open at the end, of delivering a rather forcible direct stream of water through that opening, a thing to be avoided in delicate states of the gastric mucous membrane.

Recently flexible tubes of silk have been introduced, but they possess no advantage over the rubber tubes, and are considerably more expensive.

Various forms of suction apparatus have been proposed at different times for emptying the stomach, but these have all been superseded by the syphon. This consists of the stomach-tube above described, to which a funnel is attached by means of a second rubber tube somewhat longer than the stomach-tube proper. The two rubber tubes are usually united by a piece of glass tubing of equal calibre, so that the lumen of the whole syphon may be the same throughout. Such a stomach-syphon is shown in the accompanying cut.

The principle upon which the proper working of this tube depends is that of the ordinary syphon. When the stomach-tube is passed, and the tube is filled with water by means of the funnel, lowering the funnel to a position below the level of the stomach converts the tube into a syphon, and causes an amount of suction measured by the difference in level of the inlet and outlet of the tube. It will be evident that by this apparatus a most simple and accurate adjustment of the pressure employed in emptying the stomach is possible—an important consideration in some of its more serious disorders—and for this reason the stomach-syphon is to be recommended above every other form of apparatus for routine use in stomach lavage. It has the additional advantages of simplicity and portability.

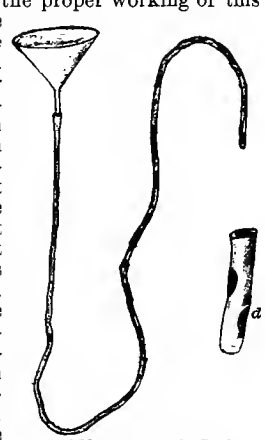

FIG. 592. — Stomach Sypbon. *d*, Tip of Tube, showing the Lateral Openings.

As a rule no great difficulty attends the passage of the stomach-tube. The patient should sit erect with the face in the median line and the head *not* thrown back. The clothes should be protected by towels. The tube, which has been previously warmed in water, is grasped in the right hand, the left being free to steady the head of the patient if necessary. No lubricant is required. The patient then opens the mouth and protrudes the tongue slightly. The tube is passed quickly backward over the centre of the tongue to the posterior wall of the pharynx. On coming into contact with this, its extremity bends downward, sliding over the pharyngeal mucous membrane to the introitus œsophagi. The contact of the tube with the pharyngeal mucous membrane usually sets up reflex spasmodic contraction of the faucial and other pharyngeal muscles, and may even give rise to rather troublesome expulsive efforts. These should not alarm the operator, however, nor cause him to desist, but should be met by him with the command to swallow. A determined effort of the patient to obey usually quickly controls the expulsory efforts, and after passage of the extremity of the tube into the œsophagus its further progress is unattended by any hindrance, being aided by gentle onward pushing of the tube by the operator and by re-

peated efforts at swallowing. As the tip passes the cardiac orifice a slight increase of resistance may at times be appreciated, and is then of assistance to the physician in giving definite information as to the location of the cardiac orifice, a factor of some importance in determining the exact size of the stomach. After passing the cardiac orifice, the tube should be pushed on until eight or ten inches of it have passed into the stomach. Its extremity should then lie along the greater curvature of the stomach, pointing toward the pylorus.

During the passage of the tube, and so long as it remains in position, the patient should be made to breathe deeply, and while this is possible the operator has assurance that everything is going well. The quite universal dread that the tube may pass into the larynx is, in the opinion of the writer, quite unfounded, that accident never having occurred to him. It is, furthermore, unattended with serious results, as the stoppage of the larynx is at once indicated by violent cough, by the inability of the patient to breathe, and by commencing cyanosis, whereupon the tube should be immediately withdrawn. Usually no difficulty of respiration is experienced by the patient after the first insertion of the tube.

There is an instinctive tendency on the part of the patient to throw the head back as the tube is being passed. This should be forbidden, and, if necessary, prevented by steadying the head with the left hand. Extension of the head causes material narrowing of the upper portion of the œsophagus, thus imposing increased resistance to the passage of the tube.

Excessive sensitiveness of the pharyngeal mucous membrane in neurotic individuals may rarely necessitate painting of the posterior pharyngeal wall and fauces with an anæsthetic. For this purpose a ten per cent. solution of cocaine is to be recommended. It should be applied with a camel's-hair brush about ten minutes before the tube is passed. The writer has found the mucous membrane of the fauces, in nearly all cases, much more sensitive than that of the posterior pharyngeal wall, and it is his habit to avoid irritation of the fauces as much as possible by carefully passing the tube in the median line, allowing it to come into contact with the upper surface of the tongue only before reaching the posterior pharyngeal wall. Of course this is not always possible, as some patients raise the tongue as soon as anything is felt to touch it, thereby usually pushing the tube to one side; but by a little attention to the above suggestion, much of the reflex spasm often produced by less careful efforts to pass the tube may be avoided.

The insertion of the finger of the operator into the mouth of the patient is entirely unnecessary.

In the hands of an experienced manipulator there may be said to be no valid contra-indication to the passage of the stomach-tube. Nevertheless, its employment is by no means always to be advocated in disorders of the stomach, and there will be many occasions when the judicious physician will refrain from its use. He will, for example, spare his patient the slight discomfort attendant upon its passage in cases where neither diagnostic nor therapeutic advantage can result from its use; he will not advocate its employment in cases of extreme exhaustion from general diseases, even though attended with stomach symptoms; and he will be very cautious in its employment in cases of advanced heart disease, when aneurism of any of the larger arteries is present, and immediately after hæmorrhage from any of the internal organs, especially from the stomach, whether the result of ulcer or carcinoma of that organ.

As has been already said, for all ordinary purposes of stomach lavage the syphon is to be recommended above every other form of apparatus. The tube having been passed the funnel is held in the left hand at about the level of the patient's head, and is slowly filled with water of about the temperature of the body or only slightly cooler. As it flows out of the funnel into the stomach the funnel should again be filled, and this should be repeated until the desired quantity of water has been introduced or the patient experiences a sense of uncomfortable fulness in the epigastrium. While still partially filled the funnel should then be lowered to a point below the level of the lower border of the stomach, when the water introduced into the stomach, together with the previously contained remnants of undigested food and mucus, will flow out through the syphon thus formed into the pail or other receptacle which has been provided for its reception. This procedure should be repeated until the wash-water comes away perfectly clear. If this result is finally accomplished the amount of wash-water which may have been required is a matter of little importance. Nevertheless, the amount introduced at each washing, as well as the amount returned, should be measured in order to make sure that all the water introduced has been removed from the stomach before the removal of the tube.

Not infrequently the return of the wash-water will be quite suddenly interrupted before the complete emptying of the stomach. This may result from stoppage of the openings in the tube by solid particles of food too large to pass through them, or from the entrance of gas contained in the stomach into the tube, thereby interfering with its action as a syphon. When through the glass tubing uniting the rubber tubes of the syphon it is seen that the tube is still full of water, it is fair to infer that particles of food are blocking the openings of the stomach-tube. Under these circumstances the simple deeper insertion of the tube may serve to dislodge the obstructing particles, or the effort may be made to draw them through the eyes of the stomach-tube by increasing the suction upon them either by lowering the funnel, thus lengthening the long arm of the syphon, or by means of a rubber bulb or other suction apparatus. The writer has found the following manipulation to accomplish as much under these circumstances as more elaborate suction apparatus. It is much simpler and is believed to be devoid of all danger. The rubber tube constituting the long arm of the syphon is tightly grasped near the glass connecting tube by the left hand of the operator, and is drawn between the thumb and index-finger of the right hand, which should compress and force all air out of the portion of the tube drawn between them. On relaxing the pressure exerted by the left hand the contents of the stomach end of the tube rush in to fill the portion of the tube from which the air has been expressed and thereby exert suction at the openings of the stomach-tube, which in most cases is sufficient to dislodge the obstructing particles. If after repeating this manipulation the syphon action is not re-established a little water may be poured into the funnel and allowed to run into the stomach, in doing which it will often dislodge the obstruction. If this, in turn, is unsuccessful, there is nothing to do but to remove the tube, clean it, and reinsert it.

When it is evident that the presence of air in the syphon is the cause of its non-action, deeper insertion of the tube and filling the funnel again with water, will in the majority of cases serve to re-establish the syphon without further trouble. It should, however, be remembered that, if inserted too far, the tube may bend upon itself and its extremity may in consequence come above the surface of the liquid, thus permitting the entrance of air. If, therefore, the syphon still fail to work after its deeper insertion and filling, the tube should be slightly withdrawn and the effort to syphon repeated.

It is of much importance that the stomach should be thoroughly emptied at the end of the lavage, and every effort should be made to accomplish this result. The irritation caused by even a small amount of residual wash-water may often be sufficient to materially interfere with the beneficial effect of the lavage.

When prolonged use of lavage is necessary the patient frequently becomes so accustomed to the passage of the tube, etc., as to be able to carry out the treatment himself without the aid of the physician.

In the great majority of cases plain water meets all the requirements of lavage, but occasionally advantage is gained by the use of weak saline solutions or mild antiseptics. The most frequently employed salts are sodium chloride (one per cent. solution), sodium bicarbonate or carbonate (two to five per cent. solution), and Carlsbad salt or water. As mild antiseptics the following

may be used: Boracic acid (three per cent. solution) or borax, sodium salicylate (one-half to one per cent.), sodium benzoate (one to three per cent. solution), creolin (fifteen drops to a quart of water), and chloroform water.* It is almost superfluous to say that the more powerful and poisonous antiseptics, as carbolic acid and bichloride of mercury, should not be made use of for lavage.

The sovereign indication for lavage is the presence in the stomach of deleterious material, whether this be poisou, imperfectly digested and fermenting food, or other retained and irritating substance, and whether its presence be due to hindrance of its onward progress into the duodenuum or is the result of inefficient gastric digestion.

In the majority of cases of acute poisoning it is the imperative duty of the physician to empty the stomach of his patient as speedily as possible, and where there is any possibility of his deriving benefit from that procedure there can be no contra-indication to the use of the stomach-tube. Often it is greatly to be preferred to an emetic, both on account of the slow action of the latter in many cases, notably in opium poisoning, and because the evacuation of the stomach by the tube may be made much more thorough. In the case of opium poisoning the lavage should be frequently repeated for at least two hours, as recent investigation has demonstrated that morphine, even when administered hypodermatically, is eliminated in considerable proportion through the mucous membrane of the alimentary tract, particularly of the stomach, and may afterward be reabsorbed.

In arsenic poisoning the intense inflammation of the gastric mucous membrane induced by the irritant action of the poison, has been regarded by many as a valid contra-indication to the emptying of the organ by lavage. If carefully performed, however, it can do no harm at all commensurate to that which is being caused by the presence of the arsenic, which latter should be removed as speedily as possible at all hazard.

In cases of poisoning by concentrated mineral acids and by some of the more corrosive organic acids, as, for example, oxalic acid, the irritant and corrosive action of the acid is so immediate and complete as to reduce the benefit derivable from lavage to a minimum, and the physician will preferably resort to the administration of large draughts of alkaline waters, with the object of diluting and neutralizing any residual acid.

In poisoning by strychnine the passage of the soft tube may be very difficult, owing to the general convulsions stimulated by efforts to pass the tube and the intensity of the trismus oftentimes present. In such case the jaws should be held apart by a strong metal gag, and it may also frequently be necessary to substitute the stiffer "gum-elastic" tube for the more flexible rubber one.

In profound alcoholic stupor and in delirium tremens, great benefit usually results from removal of the sour, irritating liquid usually filling the stomach, unless vigorous emesis has previously occurred. As in all cases of profound narcosis, great care should be taken to prevent any entrance of the contents of the stomach into the larynx by tightly compressing the tube during its removal, thus rendering escape of its contents impossible.

In intestinal obstruction from whatever cause, lavage has recently been warmly advocated by Mahnert, who supports his recommendation by the report of eight cases in which it was employed by him with marked benefit. In all the cases stercoraceous vomiting was controlled, the feculent material in the stomach and upper portion of the intestine was removed, and the condition of the patient was much improved. In three cases, after repeated washings the obstruction disappeared, and recovery quickly followed. When obstruction is the result of constriction of the lumen of the intestine by a neoplasm, lavage can of course be only palliative, but in those cases in which the obstruction is due to a twist in the gut with accumulation of a feculent mass above the point of constriction, thus intensifying the mischief already done, it appears in many cases to exert a decidedly curative influence. This is attributed by Mahnert in part to the relief of pressure above the constriction resulting from emptying the stomach and upper intestine, and in part to the stimulation of a healthy peristalsis which tends both to force the fecal accumulation upward into the less choked intestine and also to remove the primary cause of the obstruction. Whatever may be the correct explanation of the relief obtained, certain is it that lavage is often followed by marked amelioration of the symptoms in many of these cases, and its trial is unquestionably indicated, though in many cases it will be found necessary to couple it with other treatment.

In gastro-intestinal disorders of children lavage of the stomach has been attended with most signal success. The investigations of Escherich and others into the etiology of the summer diarrhœa of infants, and careful study of cholera infantum, have shown both to be due in great part, if not solely, to intestinal fermentation caused by bacteria of various kinds. The profound general symptoms met with in these diseases are attributed to the absorption of deleterious and poisonous substances generated in the course of these fermentations, and the vomiting and purging have come to be regarded as conservative measures directed to ridding the alimentary tract of its harmful contents. With the object of aiding this effort at elimination, lavage of the stomach has been extensively used by Escherich, Baginsky, Ebstein, Seibert, Ehring, Faucher, and many others, and has been followed by such decided and often almost immediate benefit, as to have received their warmest recommendation. In the simple gastro-intestinal catarrh of infants, so common in our large cities during the summer months, a single thorough lavage of the stomach with slight regulation of the diet for a few days, is often sufficient to bring about most gratifying improvement or complete cessation of the alarming symptoms. The same may be said of the benefit derived from the treatment in cholera infantum, but here repeated lavage is usually necessary: in severe cases it may even be ineffectual unless combined with thorough lavage of the colon.

The passage of the tube in the case of young infants is not difficult, provided the head is properly held by an assistant. In very young children it is usually wise to insert the index-finger of the left hand, to insure the easy passage of the tip of the tube over the epiglottis. When this has been accomplished the finger should be withdrawn, as the tube may very easily be pushed onward into the stomach. The œsophagus of the child is, of course, too small to accommodate a stomach-tube of the usual size, and an ordinary rather thick-walled, soft red rubber catheter, will be found to answer every purpose. If desirable a second eye may be cut in the side of the catheter, care being taken to smooth its edges. As with the adult, the lavage should be continued until the returned wash-water is quite clean.

We come now to the consideration of lavage as a therapeutic measure in disorders of the stomach itself. The principal conditions in which its employment in these cases is indicated, may be classed under two heads: 1. Mechanical hindrance to complete emptying of the stomach. 2. The accumulation of substances in the stomach which impede or stop the natural process of digestion.

It should be remembered that while either one of these conditions may exist alone, they are very frequently associated.

By far the most important condition giving rise to incomplete emptying of the stomach is dilatation of that organ, gastrectasia, whether the result of inefficient motor activity of the gastric wall dependent upon chronic gastritis and atrophy of the gastric mucous membrane, or the result of obstruction at or near the pyloric extremity by tumor or cicatrix of any kind. All of these conditions bring about retention and stagnation of the ingesta, and the resulting fermentation both intensifies the gastric disorder and furnishes toxic material, the ab-

* Prepared by shaking a little chloroform with a quart of water, allowing separation of the two liquids, and pouring off the supernatant chloroform water. This should be used at once.

sorption of which induces more or less derangement of the whole process of nutrition. For this condition nature herself suggests the needed remedy, in the copious and frequent vomiting which inevitably becomes a prominent symptom in those cases of dilatation of the stomach which are left untreated. Formerly attempts to rid the stomach of its noxious contents by means of cathartics constituted the accepted treatment, but we are now possessed of a far superior and almost indispensable agent in the stomach-syphon. It is not to be inferred, however, that lavage is to be employed in every case of atony of the stomach with consequent impairment of its motor activity. Diet and drugs may often overcome this difficulty, and should always be first given a fair trial. But in advanced dilatation lavage may be said to be indispensable, and the relief experienced by the patient is usually most gratifying. Flatulence, eructations, and other dyspeptic symptoms cease. Vomiting, if it have existed, is controlled. Constipation, often very obstinate, is relieved. And the cerebral symptoms dependent upon poisoning of the system by products of fermentation, and which are often such a source of alarm to the patient, usually quickly disappear. Unfortunately, however, the treatment is palliative only in the majority of cases, and its interruption is almost certainly followed sooner or later by return of the symptoms. It should, therefore, be patiently persisted in. As has been hinted before, the patient may learn the necessary manipulation and so be able to carry on the treatment himself, advising with his physician, however, at stated intervals. Daily lavage, undertaken six or seven hours after the principal meal of the day, is usually accredited with the best results, and should always be urged in every case of pronounced dilatation. In milder cases and after amelioration of the symptoms of severer cases, it may be sufficient to thoroughly cleanse the stomach every alternate day. Great care should be taken to completely remove all residue of the wash-water, as even a small quantity left in the stomach may be sufficient to wholly prevent or greatly diminish the beneficial result. In cases in which fermentation is an important factor the last wash-water may often, with much advantage, consist of a weak solution of borax (two to four per cent.), salicylic acid (three to five per cent.), chloroform water, or other anti-fermentative.

The accumulation in the stomach of substances which impede the normal process of digestion constitutes an important indication for their removal, and usually lavage is the most prompt and efficient means of so doing. Thus the acid dyspepsia dependent upon excessive secretion and accumulation of gastric juice in the stomach, is usually immediately relieved by lavage with a weak solution of soda. The interference with digestion resulting from accumulation of mucus in the stomach in chronic gastric catarrh, or in cases where much mucus is swallowed, may oftentimes be entirely removed by an occasional washing of the stomach. For this purpose weak acid solution and lime-water usually give the best results. The advantage gained by the removal of fermenting material from the stomach has already been alluded to in discussing the use of lavage in gastrectasia. Other more or less toxic substances may accumulate in the stomach in carcinoma of that organ, in uræmia, and in pernicious anæmia, and their removal is often attended by considerable relief to the patient.

From what has been said it will appear that stomach lavage is neither an universal panacea, nor is it even indicated in all diseases of the stomach itself. In ulcer, which is often unassociated with decided catarrh of the gastric mucous membrane, no benefit is usually to be expected, and the danger of inducing hæmorrhage should be remembered. Again, in some acute conditions of the stomach, as, for example, in acute gastritis, it may do positive harm by irritating the inflamed mucous membrane and so intensifying the disease. But, judiciously employed in cases in which benefit may rationally be expected from its use, it must be regarded as one of our most valuable and most reliable therapeutic measures. In Germany it is already very extensively used, and in this country the circle of those who have become convinced of its efficacy is rapidly widening. It is no longer a new, untried, or dangerous procedure, having passed from the realm of the theoretical into that of the eminently practical. *John Slade Ely.*

STOOLS, DIAGNOSTIC VALUE OF, IN THE DIARRHŒAS OF EARLY LIFE.* A careful study of infant stools usually affords a simple working classification that will prove valuable in the treatment, if not always unerring in the prognosis, of diarrhœa. The vast majority of cases of infantile diarrhœa may be included under one of three heads, viz., the diarrhœa of acute indigestion, the diarrhœa of inflammation, and the diarrhœa of chronic indigestion or atrophy.

Acute Indigestion.—In the diarrhœa associated with this affection the stools are more or less profuse, consisting at first of fecal matter, but later becoming serous as a result of the hypersecretion of the intestinal glands and of the greatly increased peristalsis. Scattered here and there are seen small masses of undigested casein and fat, and soon, if this condition continues, thin mucus may be found. Occasionally the stools acquire a greenish tint. If starchy food have been taken it will often appear unchanged in the discharges. In the summer, owing to the depressing effect of the heat upon the splanchnic nerve, there may be copious yellow watery stools when the intestinal indigestion is actually quite moderate in degree. In very acute cases there may at first be a moderate elevation of temperature, but this soon subsides, unless the indigestion passes into actual inflammation. When the latter condition supervenes, the fever persists.

Acute Inflammation.—It is a difficult matter to determine just when the irritation of the intestinal tract has passed into true inflammation, as one condition merges so gradually into the other, but when once the catarrh is fully established the diagnosis is usually clear enough. As before stated, the temperature remains elevated, and the discharges ordinarily become more frequent, the character of the latter depending in the beginning largely upon the nature of the food. When the diet consists of milk the stools will be found to contain particles of fat and coagulated casein, mixed possibly with altered epithelial cells, forming masses of putty-like appearance. When meat broths, with or without milk in very dilute form, are given, the stools are apt to become very dark-colored, watery, and exceedingly offensive. The presence of mucus is a sign of considerable value, and it is almost always present if the diarrhœa continue for any length of time. According to Nothnagel, it is difficult or impossible to detect mucus on ordinary inspection when the catarrh involves the jejunum and ileum only. Under the microscope, however, it can be seen as little islets floating in the substance of the discharges. When these little masses of mucus are stained with bile-pigment, they become, of course, much more distinctly visible, and this is an indication that the inflammation involves the small intestine as well as the large. When the upper part of the colon is affected together with the ileum, this bile-stained mucus will be mixed with particles of undigested food and fæces, and the degree of admixture will afford a tolerably correct idea of the portion of the colon most affected. The more intimate the admixture, the nearer the lesion is to the ileum, but when the mucus is passed in glairy masses, or in shreddy particles looking almost like false membrane, the disease will be found located in the lower part of the colon. The condition of the blood passed with the stools also furnishes an indication of the seat of the lesion. Thus, when it is present in dark sticky masses it has come from the upper part of the bowel; when mixed in streaks with mucus and fecal matter, it is from the upper colon or the ileum; but when red in color and not intimately mixed with the other intestinal contents, it points to a lesion of the lower colon or rectum.

It is important to note the color of the stools. When

* The present article is based largely upon one which I published on the same subject in the New York Med. Journal (Oct. 29, '92). H. D. C.

they are white and of putty-like consistence they will be found to consist principally of fermenting fat; when brown, of albuminous matter from broth; or this color may be caused by bleeding in the upper bowel or by drugs, such as iron or bismuth. Red discharges are an indication of hæmorrhage from the lower bowel, and watery yellowish stools are composed of ordinary fecal matter diluted with the secretions of the intestinal glands. The significance of green stools has been variously stated by different writers, but, however caused, I have found them clinically in connection with signs of great irritation of the intestine and of fermentation of its contents.

While the character of the stools furnishes us with a fairly reliable indication of the seat of the lesion, it does not tell us much of its nature. We are often unable, for example, to satisfy ourselves of the presence or absence of ulceration of the bowel from a simple inspection of the discharges. Eustace Smith says that a shreddy deposit mixed with small black clots of blood in the stools is a symptom of ulceration, but I have found it by no means a reliable sign of this condition, and have often been surprised to find ulcers on autopsy that were unsuspected during life. For example, a large flabby child, seven months old, was admitted to the babies' ward of the Post-graduate Hospital, with a history of vomiting and frequent stools. She had been fed for five months on cow's milk. A moderate diarrhœa continued for ten days without any unusual features, the temperature not rising above 100° F. She exhibited a continuous failure of vitality, however, in spite of taking and apparently digesting her food fairly well. She died suddenly, and the autopsy revealed numerous ulcers in the lower two feet of the ileum, while the colon was dotted with ulcers throughout its whole length, some even extending through the muscular coat; but there were no perforations. No other lesion was found except a passive congestion of both lungs. In cases in which there is a rapid loss of vitality not to be accounted for by the character and frequency of the intestinal discharges, I have come to suspect more or less extensive ulceration. When there is other evidence of tubercular infection, the presence of diarrhœa with much prostration should lead one to look for tubercular ulceration of the intestine.

Cholera Infantum.—This condition presents a striking contrast, when we consider the violence of the symptoms and the paucity of lesions found after death, to the diarrhœa depending upon ulceration. The great difference between this and all other forms of diarrhœa in children, leads us to the belief that its cause is to be found in the presence of a specific germ. The disease begins often as a simple diarrhœa accompanying intestinal indigestion. After these symptoms have existed for several days the stools suddenly become very copious and watery, barely staining the diaper, but imparting to it a peculiar musty odor. Vomiting soon sets in, everything, even water, that is taken into the stomach is rejected at once. The tissues are quickly drained of their fluids and become so shrunken that the child is hardly recognizable. The sphincter is relaxed and the discharges ooze away almost uninterruptedly. The skin is cold and clammy, and convulsions or coma often precede death. This disease is fortunately not of common occurrence, only a small proportion of the diarrhœas of children seen in the summer months being of this form.

Chronic Indigestion and Atrophy.—The diarrhœa depending upon this cause is one of the most obstinate and difficult to treat of any occurring in childhood. It affects chiefly cachectic infants whose hereditary history is bad or who have been unwisely fed, and who live amid unhygienic surroundings. They may be the subjects of syphilis, rachitis, or tuberculosis. In other cases, however, none of these diseases is present, but the infant simply falls away despite the most careful attention to its diet. The discharges are usually offensive and consist largely of fermenting food, but they may not be numerous. Their appearance changes from time to time, putty-like stools alternating with green or brown discharges which are mixed with mucus and of an offensive odor. The sudden appearance of one or two copious serous discharges is of evil prognostic import. The child may take food readily, as the stomach is often but little affected, and occasionally a decided change for the better may be noted; but this is only temporary, for the digestion and assimilation of the food taken seem to be impossible, and the infant soon relapses into a worse condition than before. As death approaches the stools become thinner and more frequent, and emaciation progresses steadily. The temperature is usually subnormal during nearly the entire course of the disease. At autopsy the intestinal mucous membrane is seen to be rather pale and flabby, but evidences of active inflammation are absent. The epithelium is seen under the microscope to be in a state of fine granular or colloid degeneration, and the lymphoid bodies are somewhat swollen. The underlying condition, which may be either hereditary or acquired, is an essentially defective vitality. When the vital powers are low the organs of digestion and assimilation are the first to suffer in function, from feeble innervation. Hence the uselessness of astringent, antiseptic, or any other kind of drugs in these cases.

Henry Dwight Chapin.

STRONTIUM. In 1890, Dr. Labord recommended strontium in the place of potassium as a base in the formation of various salts, its advantage being an absence of all unfavorable effects upon the system when administered for a prolonged period. It is well known, from experimental research, that potassium salts will produce paralysis of sensibility and motion, collapse, and asphyxia; and upon the heart it acts by slowing the circulation, and finally paralyzing the cardiac muscle. The salts of strontium were found to be perfectly innocuous. Labord performed his experiments upon animals, and in a few instances upon man, using the various salts of strontium and comparing the effects with the similar salts of potassium. The salts were used by intra-venous, endermic, and intra-muscular injections, and also by introducing them into the stomach by means of an œsophageal tube. Very large quantities were administered without producing any local irritation or causing any derangement of the system. Upon the heart it exerted a stimulant action, increasing the strength and force of the beat, upon the digestive organs it also acted as a stimulant, and under its influence the appetite and general condition of the patient improved. All the salts, but especially the lactate and tartrate, were found to exert a diuretic action, although not in a very marked degree.

After the appearance of Dr. Labord's communication, the salts of strontium were extensively used in the French hospitals, and numerous clinical reports were made by Dujardin-Beaumetz, Sée, Paul, and others, all very favorable to them as therapeutic agents, and confirming the statements as to their harmlessness. Their stimulating effect upon the digestive organs led to their employment in various dyspeptic troubles, in which they proved of decided value. In cases reported they caused a rapid improvement in the gastric disturbances accompanying cardiac and renal disease, and also in the various forms of dyspepsia in which hyperacidity, flatulence, and pain were prominent symptoms. They have also acquired a reputation as a valuable anti-emetic remedy. They have proved useful in nearly all forms of vomiting, and some remarkable results are reported of their use in the vomiting of pregnancy. They have also been of benefit in the vomiting of acute and chronic gastritis, the vomiting occurring in the puerperal period, and in hysteria. To relieve this troublesome symptom, thirty grains should be given immediately before or immediately after meals.

For all stomachic disorders the bromide of strontium is the salt usually selected, as it is most soluble, and has been found to be more active than the other combinations. It is given in doses of fifteen to thirty grains, repeated three or four times a day, and has been given to the extent of five or six drachms in the twenty-four hours without causing any ill effect. As the salt is very hygroscopic it requires to be given in solution. It possesses a rather

unpleasant taste, which may be disguised by syrup of orange.

The bromide has also been used as a substitute for potassium bromide in the treatment of epilepsy. The dose in these cases is thirty grains every three hours. Although it contains less bromine than the potassium salt, it is said to prove equally efficacious in controlling the attacks. Its main advantage is its freedom from the local irritating action and depressing effects of potassium. Whenever there is any gastric irritability, or when bromides have to be administered for a prolonged period, it is very superior to the other salts.

As a diuretic it was found to be serviceable, but its effect upon albumin, when present in the urine, proved much more important. Its employment in this condition was found to cause a rapid diminution in the amount excreted and to cause improvement in the patient's condition. Beaumetz reports five cases, in one of which the albuminuria was due to nephritis, and in the others to heart disease. In all the cases there was within four days a diminution in the amount of albumin of one-half, and an amelioration of all the symptoms. Many other cases have been reported in which it was equally beneficial. It appears to be particularly useful in the albuminuria of chronic heart disease and in that occurring during gestation. It has not been as successful in cases of acute nephritis, and should not be used where there is much destruction of renal tissue. In chronic parenchymatous disease it appears to be more beneficial than in the interstitial form. Its beneficial effects are explained by its general tonic and alterative action. By its action on the excretions it relieves the system of much morbid material, and the improvement in the digestive organs reduces the formation of toxines to a minimum.

Quite recently the iodide of strontium has been suggested as a better means of administering iodine than the iodide of potassium. It has proved useful in many forms of heart disease, relieving the anasarca, dyspnœa, angina, and other distressing symptoms. It is much better tolerated than the potassium salt, and its beneficial effects are rapidly manifested. It does not appear to have been used in syphilitic diseases. The dose is the same as that of the other strontium salts.

Beaumont Small.

STYRACOL. CINNAMYL-GUAIACOL. A German patented compound of guaiacol and cinnamic acid. It is described as the cinnamic-acid extract of guaiacol, and is obtained by mixing molecular proportions of cinnamyl chloride and guaiacol, and heating the mixture in a water-bath. The resultant mass is treated with boiling alcohol and filtered; as it cools, the styracol is deposited in long silky needles. Styracol possesses the antiseptic properties of its constituents, and was introduced as a substitute for guaiacol (q.v.). It has been used for the treatment of tubercular disease, and for catarrhal affections of the gastro-intestinal tract, vesical catarrh, and gonorrhœa. It has not been employed to any extent, and its therapeutic value cannot yet be estimated.

Beaumont Small.

SULPHAMINOL. A new antiseptic said to be formed by the action of sulphur upon certain salts of the aromatic series. In the body it is supposed to decompose into carbolic acid and sulphur compounds. It was introduced for the purpose of replacing iodoform, on account of its active antiseptic action and freedom from odor. It is a pale yellow powder, without taste or odor, insoluble in water but dissolved by the addition of alkalies; it is soluble in alcohol. When subjected to heat it turns brown and melts at about 155° C. The dose for internal administration is four grains three times a day, but it does not appear to have been used to any extent. To test its therapeutic value a series of experiments were made by Wojtaszek, a Polish physician. Rabbits were selected and the drug was either injected under the skin or given internally, in doses equal to three or four grammes per kilogramme of the animal's weight. He found that, 1, when injected hypodermically, the substance formed a foreign body which became encapsuled in a few days; 2, when given by the mouth, it was eliminated with the fæces without undergoing any decomposition; 3, in neither case did the drug give rise to any physiological effect, except a trifling congestion of the gastric mucous membrane when given internally.

Externally, it has been used in all cases in which iodoform is employed. It has proved of service in the treatment of ulcers, wounds, etc., and appears to possess a desiccating action upon suppurating surfaces which greatly hastens their healing. It has been used with very marked success in affections of the nose and throat, and in abscess of the antrum. In the form of a powder, it is blown into the cavity, or on the diseased surface, and rapidly checks any offensive discharge and hastens repair.

Beaumont Small.

SULPHONAL. This hypnotic has attained a position second only to chloral hydrate, and in the opinion of many is superior even to that well-known drug. It has proved itself to be purely a soporific, and is rarely employed for any other purpose than to procure sleep. The usual properties which are so common to the newer drugs are wanting in this. It does not influence the body temperature, it has no antiseptic qualities, and as an analgesic is of no practical value. Unlike other narcotics, it has no period of excitement, does not check or alter the secretions or derange the digestive organs, and is almost without any influence upon the heart or circulation. Devoid of these many disadvantages, its success as an hypnotic is readily understood.

Sulphonal has proved of greatest service where the insomnia is of purely nervous origin, as in neurasthenia, mental depression, over-work, and worry, and has found a field of great usefulness in the various forms of mental disease. It is in the latter class of cases that it is most used, and asylums throughout the world employ it very extensively. When pain is the cause of the sleeplessness, its good effects are greatly modified, but in many forms of neuralgia and pain of a reflex character it may be used with success. Experiments upon animals have demonstrated that it exerts, in a moderate degree, a sedative effect on the spinal cord, lessening the reflex function, and also modifies the action of the motor and sensory nerves. Where pain is due to organic disease it has no influence whatever. In the insomnia of acute and chronic disease, and during convalescence from disease, it is of much benefit, but requires to be given with some caution, particularly when there is much debility or prostration. In the sleeplessness of cardiac disease and other forms of organic or mechanical derangement, it is not of much use. In delirium tremens it has been much used, in many instances with benefit, but in these cases the effect is uncertain, and the dose required is excessive and approaching the limit of its physiological action.

As an hypnotic, the dose is from fifteen to thirty grains. It is usual to commence with fifteen grains and increase the quantity until the proper effect is produced. Ten grains will often be sufficient in the aged and debilitated, or where the insomnia is of a mild degree. Under ordinary conditions thirty grains is a perfectly safe dose, and this quantity is usually required to produce its full hypnotic action. When the drug requires to be given for a prolonged period the dose can generally be lowered, as the drug is cumulative. On account of its insolubility the action is slow, and the dose should be administered at least one hour before bedtime. Its action is rendered more rapid if the drug is finely powdered and administered in hot solution. Six or eight ounces of boiling water are recommended as sufficient to dissolve thirty grains; after it is dissolved, cold water may be added to render it sufficiently cool to be taken. Hot milk and broth may also be made use of; tea and coffee are frequently used, but they undoubtedly, to a certain extent, counteract its effect. It may also be administered in alcohol or any spirituous liquor.

The sedative action of sulphonal on the spinal cord and nerve-centres has led to its use in some nervous troubles. In chorea it has been given to children in

doses of from two to five grains, and has been followed by a fair percentage of successes. In old-standing cases it has little or no influence.

It is now fully recognized that sulphonal is not without its toxic action, and numerous fatal cases have followed its employment. The simplest symptoms that may arise generally follow the passing off of its soporific effect. They include drowsiness and stupor, giddiness, vertigo, ataxia of the tongue and muscles of the throat and face, and of the extremities. These symptoms gradually disappear after an interval of ten or twelve hours, without leaving any ill effects. The symptoms of toxic action generally appear after large doses, or more frequently after repeating an ordinary dose of thirty grains two or three times. In some instances, when the patient is debilitated and the subject of some wasting disease, very small doses may be followed by these symptoms. They appear to be due solely to the action of the drug on the nervous system, the heart and respiration are not depressed or altered, and very rarely is there any alteration in the appearance or quantity of the urine.

The fatal cases that are reported are due to overdoses or to the prolonged use of the drug.

In one case (*British Med. Journal*, October 25, 1890) the patient was supposed to have taken about an ounce of sulphonal. The stupor which followed deepened into insensibility and anæsthesia, the pupils remaining normal and acting to light, while the conjunctiva was insensitive. Breathing was natural, pulse very slightly disturbed, but the temperature ranged between 100° and 103° F. A profuse perspiration bathed the body, and there was total suppression of urine after the first day. On the third day the breathing suddenly became short and jerky and ceased altogether. Another case is reported (*Medical News*, August 10, 1890) in which two doses of fifteen grains, given within an hour and a quarter of each other, caused death. The patient was a young insane woman who had formerly been given large quantities of chloral, and other hypnotics. No medicine had been given on the day she took the sulphonal. She slept quietly all night, and on the following day was drowsy, but could be roused and made to talk rationally; sleep at once came on when she was left alone. The pulse and respiration were slightly accelerated and the pupils normal. Eighteen hours after taking the medicine the pupils began to contract and her temperature rose to 102° F.; in forty hours cyanosis began, and she died from failure of respiration.

The occurrence of fatal cases following the prolonged use of sulphonal, is evidently much more common. Lépine (*La Semaine Médicale*, January 20, 1893) has collected a series of thirteen cases terminating in death. These patients had taken the drug for periods varying from sixty to over a hundred days in ordinary doses. Severe symptoms suddenly supervened and death followed within a few days, although the medicine was stopped at once. The prominent symptoms were gastro-intestinal disturbances, symptoms referable to the nervous system, such as failure of co-ordination, difficulty in speech, and diminution of the reflexes; diminished secretion of urine, which became of a peculiar red color and contained biliary pigment, mucin, and albumin, with leucocytes, numerous red cells, and epithelial casts. In these cases the drug was well borne until the toxic symptoms set in. The disturbances of the digestive organs generally masked the nervous symptoms, and the fatal termination was due to heart failure with œdema of the lungs.

How these poisonous effects are produced is as yet uncertain. What decomposition the sulphonal undergoes after administration, or what products are formed, has yet to be discovered. At present we must hold to the hypothesis that it is the action of sulphonal on the nervous system that is to account for the symptoms of poisoning. No unfavorable changes are produced in the blood, and it cannot be classed as a blood poison. The effects upon the kidneys and urine are important, and are now receiving a great deal of attention, although they appear late in the train of toxic symptoms. One point alone has been definitely established, and that is the dangerous state the patient is in when hæmatoporphyrin (hæmatin without iron) appears in the urine. How this is produced is not known, but as soon as it is detected the administration of sulphonal should be stopped.

Beaumont Small.

SYMPATHETIC NERVOUS SYSTEM. The opinion expressed in the HANDBOOK, Vol. VIII., p. 506, that the sympathetic nervous system is an outgrowth from the cerebro-spinal, has been called in question by the researches of Paterson upon embryos of small mammals, particularly of rodents. He finds that the main sympathetic cord develops independently as a cellular rod or column without any sign of ganglia, and that the connection of the spinal nerves with it occurs secondarily. The formation of the ganglia is subsequent to this. He therefore holds that the sympathetic cord is primarily unsegmented.

The most striking of the conclusions of Paterson is, however, that the sympathetic is not formed from the ectoderm as are the structures of the nervous system, but unmistakably (as he supposes) from the mesoderm. This is distinctly opposed to the views advanced by Balfour and Onodi.

Paterson suggests that it is quite possible that the sympathetic nervous system may comprise two independent apparatuses, one the sympathetic system proper, derived from the mesoblast, and another an offshoot from the cerebro-spinal system. In support of this he adduces the histological character of the nerve-cells, those of the spinal ganglia being rounded, while those of the ganglia of the sympathetic chain are angular. He calls attention also to the fact that these latter cells appear to have a regulating or trophic function, rather than one that is automatic or reflex. Part of the sympathetic system appears also to be employed in the construction of the supra-renal bodies, a matter that is certainly very foreign to anything now known concerning the behavior of the cerebro-spinal system.

It is not likely that Paterson's views will be accepted without challenge. In the meantime, however, the histologists who, by the Golgi method of impregnation, have already done so much toward advancing the knowledge of the anatomy of the central nervous system, have turned their attention to the spinal and sympathetic ganglia.

Some of the features of the spinal ganglia have been referred to in the article on cranial and spinal nerves in this volume. These ganglia are, in the main, composed of certain large, rounded cells, termed gangliоblasts, which are primitively bipolar, sending one process to the periphery of the body and another toward the central nervous system, where it gives off collaterals at different levels.

The ganglia of the sympathetic have hitherto been described as consisting of multipolar cells which differed from those of the cerebro-spinal system in that each was connected with a nerve-fibre. Ramón y Cajal and Retzius have shown that this is not the case. There is always a long axis-cylinder process and several short or protoplasmic processes, and thus is here confirmed the general law of structure for the nervous elements.

There is a striking similarity between the cells of the ganglia of the sympathetic chain and those of the anterior horn of the spinal cord. There are the same short processes distributed in the vicinity of the cell, and the long process which passes out to make up the interganglionic cord, and sends its ramifications probably as far as the viscera, giving off collaterals which may be used to correlate other cells.

From the spinal cord there come by way of the anterior roots, centrifugal fibres that terminate in each sympathetic ganglion by free ramifications.

Ramón y Cajal found that most of the short fibres of the sympathetic cells are disposed around the bodies of other cells in a peculiar manner, making what he terms a pericellular nest (Fig. 593).

This however is considered by Van Gehuchten to be merely an accidental phenomenon.

The cells of the visceral ganglia of the sympathetic have also been examined by means of the new methods. There are found, in the plexuses of the intestine, in the walls of arteries, and in the stroma of glandular organs, small nerve-cells scattered here and there and giving off processes that ramify again and again, and end by free ex-

tremities among the muscular or epithelial elements. These appear to be similar in character to those that collect impressions from the retinal rods and cones, and from the mucous membrane of the auditory passages. Such cells I have elsewhere called æsthesioblasts. If further investigations show that this structure is general throughout the distribution of the sympathetic nervous system, it may then be concluded that there are here certain elements that perform for these mesodermic and entodermic surfaces the same functions that the æsthesio-

blasts do for the ectodermic, and to such elements the name splanchnoblasts might be applied.

Much yet remains to be done with regard to the details of distribution. Berkley has shown that the mucous membrane of the small intestine is supplied wholly from the plexus of Meissner, the nerve-bundles giving off collaterals to the muscularis mucosæ, and ending in small expansions that he considers as homologous with motor plates. The small rounded knobs found immediately beneath the epithelial covering of the villi, which were considered by Ramón y Cajal to be nerve-cells, are thought by Berkley to be homologous with tactile corpuscles.

SYMPHYSEOTOMY.—Section of the symphysis pubis during parturition, where there is not sufficient pelvic space to admit of the passage of the fœtus without seriously endangering its life, has quite recently, after subjection to a long and persevering trial, become, under antiseptic management and a rigid technique, one of the established and approved operations of surgical obstetrics. For more than a century it held a position of very bad repute, and in France, where it originated, it was only performed twice during a period of seventy years, down to February, 1892. In Germany it was abandoned after a few trials, and was not resumed, except once in 1852, for fifty years, or until April of this present year. For one hundred and fifteen years it was rejected and condemned by the obstetrical teachers of the United States, and was never performed until September 30, 1892; since which date five successes in order, in less than ten weeks, have made it the talk of the profession. We wish no better evidence in its favor than the fact that forty-eight women have been operated upon in order since January 1, 1886, in Italy, with only two deaths.

To Dr. Sigault, of Paris, is due the credit of having inaugurated the operation in the year 1777. We can now say *credit*, as to his scheme of opening the pelvis, although obstetricians the world over were, for a century, inclined to attach to his memory epithets that were far from complimentary. We now give him credit for his scheme of enlarging the pelvic calibre, and for this only, for the reason that the operation of to-day has discarded every step in his original technique, and has superaddcd antiseptic precautions, to the great reduction of maternal deaths, as evinced by the fact that fourteen women were lost out of the first forty operated upon, covering a period of twenty-six years, or thirty-five per cent., against a loss of twelve per cent., which is the present general mortality.

The first change in the method of operating was the substitution of the subosseous division of the symphysis, cutting from within outward and below upward, for the direct section through the mons veneris and symphysis, which caused a greater hæmorrhage and endangered the integrity of the bladder or urethra. This was tested in Spain at a very early period (August 9, 1780), by Amonio Delando, of Utrera, who operated under the direction of Professor Francisco Canivel, of the University of Cadiz, upon what appears to have been the twenty-second subject in order. This was a primapara of forty-two who had been in labor for three days; her child was saved and she recovered in thirty-eight days. This improvement appears to have been either overlooked or disregarded until the time of Professor Genaro Galbiati, of Naples, whose sixteen operations cover the years 1815 to 1840, and who originated the use of the curved probe-pointed bistoury that bears his name, is still in general use, and will be until its defect of curve is appreciated under the test of experience, when a form obtained by adaptation rather than conjecture may be expected to take its place. Such a knife is already in existence, and theoretically promises to be a decided improvement over

the old form. To cut to advantage, the curve of the blade should be made to conform to that of the posterior wall of the symphysis in deformed pelves, and with the line of direction under the pubic arch, reaching a short distance beyond it in front. The curve of Galbiati's knife makes it impossible to use it upon the back of the symphysis at the first step of the operation, and the long end of the blade is apt to produce hæmorrhage by incising the veins under the mons veneris.

Professor Galbiati commenced to operate as stated in 1815, and continued his work until 1840, delivering in this period sixteen women, one of them of twins, and saving eight women, and only four out of seventeen children. During these twenty-five years, Naples had three other operations under three operators, who saved two women and two children. The last hold of symphyseotomy in its first period was Naples, where after six operations had been performed, in thirteen years, by three operators, saving five women and four children, the scheme of Sigault died out in July, 1858.

The Revival of Symphyseotomy in 1866.—In the first period of the operation there were over one hundred women delivered under it, in the eighty years during which it was performed; and it died a natural death because of its discouraging results. Too much was attempted to be accomplished under it, and hence its death-rate was high. Had the *conjugata vera* been limited in measure as it is now, and the women been delivered early in their labors, there would no doubt have been much more favorable results; as it was, there were too many deaths of mothers and children, and notably of the latter, to make the method of delivery justifiable. We have not been able to find any evidence of a symphyseotomy having been performed in any part of the world, from July 25, 1858, to February 14, 1865, at which latter date the late Professor Cesare Belluzzi, of Bologna, thought proper to make trial of it, but lost the mother by tuberculous pneumonia in twelve days. He operated a second time, on October 17th, in a case of rachitic deformity, as was also the first, and the woman died of peritonitis in six days, believed to have been purely puerperal, as was verified on autopsy. Before these operations by Belluzzi, steps had been already taken (in 1863) by Professor Ottavio Morisani, of Naples, which ultimately led to the revival of the operation, and to its performance with very little mortality. Professor Morisani, by operating upon dead parturient women, became convinced that the method of delivery was not only feasible but quite philosophical, and was prepared to look for favorable results in the living subject, in which his initial section of January 5, 1866, did not disappoint him.

The establishment of symphyseotomy as a commendable method of delivery has been the result of a long, patient, and persevering effort to reduce its rate of mortality by various steps of improvement in its performance, and the after-management of the patients. Although the introduction of antisepsis has accomplished wonders for the operation, it has only been one of the steps of improvement since the days of Sigault. This is shown conclusively by the fact that the marked reduction in the rate of fœtal death can have no dependence upon an aseptic condition in the mother. In the days of Sigault, the first thirty operations lost *eleven* women and *nineteen* children; but the same number, after the revival under Morisani, saved twenty-four women * and twenty-three children; an increase of maternal recovery from nineteen to twenty-four, and of children born alive from twelve to twenty-three. And this only represents a part of the improvement, for in the first period a woman that escaped death was often seriously disabled by lameness, or incontinence of urine, which in the second period she escaped from by a better management. When Professors Morisani and Novi began their symphyseotomies, they saved two women out of three, or ten out of the first fifteen; just as was done under Sigault and his followers; but they were encouraged by the marked improvement in the delivery of living children, eleven against three. Under the second fifteen, when all of the women were saved but one, and twelve of their children, came the encouragement to persevere and to perfect the technique. This last was not satisfactorily effected until seven years ago, when more than seventy operations had been performed (1866 to 1886) in Naples.

With January 1, 1886, commenced an era of remarkable success for symphyseotomy, so much so, that it is difficult to realize the extent of the change that has been effected. The operation had such a bad reputation among obstetrical writers, many of them still living, that it has taken an almost incredible array of facts to convince them that it has become their duty to revolutionize their opinion, and recommend what they had formerly condemned in no questionable terms. Seven and a half years of active work, covering over two hundred operations in ten countries, have shown that the method has a low grade of risk. Having seen the operation four times performed, saving all of the women and three children, I cannot but recommend it to be resorted to where deformity of the mother demands it. Its low rate of mortality makes it not only a substitute for craniotomy, but for the cases in which it becomes very doubtful whether the fœtus can be saved either under a delivery by the forceps, or after version. There are obstetricians who abhor a craniotomy, and yet are ready to take the risk of the forceps and version, where they feel that either may prove a failure. Are such men ready to prepare themselves to do a symphyseotomy in this emergency? I have just seen a quintipara a week after this operation, where the fœtus weighed over eight pounds, and the symphysis had been separated two and one-quarter inches in its delivery, whose convalescence was quite equal to that after a normal labor, and whose expression was "I do not think I could be doing any better." This woman has had two children saved respectively by the Cæsarean section, and by labor induced at eight months; the latter fœtus weighing exactly three pounds less than that delivered under pubic section.

It was thought by Morisani, in 1881, that one essential of success in forty cases out of fifty reported by him, was in the fact that three-fourths of the women were allowed to deliver themselves after the section was made; but this has been discovered to have been an error of judgment, and now, under a rigid antisepsis, the forceps is resorted to in a large majority of cases, and with a greater saving of fœtal, as well as maternal life.

It might seem strange that Professors Morisani and Novi, of the Maternity of the Hospital for Incurables, should so soon be able to reduce the mortality of the women to twenty per cent. and of the children to eighteen; but for the fact that the history of symphyseotomy shows that its early advocates were deficient in skill in pelvimetry, in obstetrics, and in the surgical management of their cases. They could not make a reliable pelvic measurement; performed the operation where the sacro-pubic diameter was entirely too short; did not suture the wound over the symphysis; and appeared to know nothing of the importance of fixing the pelvis. A great deal of the bad reputation of the operation was earned for it by a worse management of the cases. Without any antiseptic precautions, the obstetrics and surgery of the present day should be competent to save many more lives under the operation than was done in the time of Baudelocque, when eighteen women and thirty-six children were lost as the result of the first fifty operations.

Mode of Performing the Operation.—This should not be undertaken where disease has produced an ossification of a sacro-iliac synchondrosis, or where the true conjugate diameter is less than sixty-seven mm. (two and five-eighths inches); there must also be no obstructing tumor in the cervix or pelvis. The instruments required are two scalpels, a symphyseotomy knife, some hæmostatic forceps, a needle-holder and needles, a silver catheter, ligature silk, gauze, cotton, canvas bandage for pelvis, and cotton bandages.

After these have been sterilized, place the parturient woman on her back, upon an operating-table, with her

* There were six deaths out of the first thirty-six cases.

knees drawn up and separated, shave the pudendum, and disinfect the supra-pubic region, the vulva, the perineum, and vulvo-vaginal canal. Examine the depth, thickness, and direction of the symphysis, and search out the fossa in its superior edge, which marks the point of union of the ossa pubis; then examine the inferior margin, and the anterior and posterior faces of the symphysis.

Introduce the catheter and give it into the hand of an assistant who is to depress the urethra from the pubic arch, and carry it to the right side to save it from injury. The operator may stand on the right of the patient or sit between her lower extremities, as he prefers, the former being the usual position.

Make a vertical incision through the skin and fat above the symphysis, of an inch and a half to two inches in length, ending three-quarters of an inch above the pubis. Cut down to the pubis subcutaneously, and back to the attachment of the recti muscles. Separate these from the bone on either side, so that the index-finger may be admitted. Insert the left index-finger, hold it vertically,

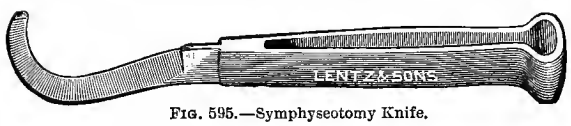

FIG. 595.—Symphyseotomy Knife.

and by rotating it to and fro, bore with it under the retro-pubic tissue down to the pubic arch, and force it under the arch above the catheter. Apply the palm face of the finger over the part to be cut through; introduce the symphyseotomy bistoury, and pass it under the finger until it protrudes beneath the arch. Incise the interosseous ligaments and cartilage from within outward and below upward until a creaking sensation indicates that the separation is effected: the bones will then be sensibly disconnected. In some operations it is quite difficult to pass the finger behind the symphysis, and occasionally it will require much force to separate the pubic bones by the knife.

When the symphysis has been divided, cover the wound with the gauze dipped in a bichloride solution of 1 to 4,000, and attend to the delivery of the fœtus, having at the same time the separation of the innominata antagonized by pressure with the hands of assistants. During the passage of the head, ascertain the width of pubic separation; spray the vagina, and when the placenta has been delivered, attend to the incised wound. Close this with six or eight interrupted silk sutures, and dress with sublimated cotton, 1 to 2,000. Bandage the pelvis with the canvas bandage, and fasten the knees together to prevent any pelvic strain.

The symphysis will sometimes reunite in a week; but it is safe to keep the woman from walking until the end of the fourth week, or until the union is solid. The time for consolidation appears to depend upon the subject, and does not seem to be influenced by the amount of separation that may have been produced in the delivery.

Some women will bear a separation of three inches as well as others will one of two. In one American case, where the gap measured $2\frac{7}{8}$ inches, restoration was remarkably rapid. In another, a separation of $2\frac{1}{4}$ inches produced no trace of gluteal pain during convalescence. The widest separation recorded in Europe (June, 1891), was $3\frac{3}{10}$ inches, and the woman was out of bed on the twentieth day. There was no injury to her powers of locomotion.

Much has been written about the mechanism of labor, after the pelvis has been opened by symphyseotomy; and diagrams with calculations prepared to show how little is gained in the antero-posterior diameter of the pelvis. This little gain has been used repeatedly as an argument against the propriety and practicability of the operation, and as an explanation of its large fœtal mortality. A flat pelvis gains in its transverse and oblique diameters, and the separation of the pubic bones gives space for the accommodation of part of the fœtal head, generally a parietal protuberance. The moulding of the head, and the pressure of the forceps, have a share also in the passage of the cranium. The fact of the low fœtal mortality during the past seven years, sufficiently attests the practicability of symphyseotomy as an obstetric measure.

The fact that a woman has previously borne living children, is no proof against the propriety and requirement of a delivery under symphyseotomy. Multipara occasionally produce children so large that they cannot be delivered through a pelvis that is under size, except with very great risk to fœtal life; or it may be, without a fatal cranial pressure under the forceps. There cannot be a maximum limit to the true conjugate, in a pelvis that is under the average size, because even with a measure of $3\frac{3}{4}$ inches, Professor Freund, of Strasburg, felt warranted in operating, after a labor of six days, where the bi-parietal diameter proved to be $4\frac{9}{16}$ inches. The operation saved both child and mother. A fœtus of eleven pounds has been delivered under symphyseotomy, through a $2\frac{5}{8}$ inches C.V. with a B.P. of $3\frac{5}{16}$, and lived. The mother was up in twenty days, and left the Maternity a few days later. The case was under the care of Professor Raffaele Novi, of Naples, in April, 1890.

Robert P. Harris.

SYNTHETIC REMEDIES. Medical science has long been indebted to chemistry for many of its best weapons with which it combats disease. Within a few years it has received an unusually large number of new ones, and nearly all from a quarter where half a century ago it would not have added to one's popularity to have predicted such a result as possible. It would have seemed like a direct blow at the doctrine of vital force. The laboratory of the chemist is fast taking the place of that of nature, as manifested in the vegetable world, so that the materia medica of the future seems likely to be one, almost or wholly, composed of synthetic products. So rapidly do these new remedies crowd upon us that it is almost impossible for the busy practitioner to even take note of their names, to say nothing of giving them anything like an extended study or trial. While each may possess some merit, the fate of all not possessing exceptionally valuable qualities must necessarily be oblivion, owing to the intense competitive struggle they are forcing upon one another. Experience is bound to eliminate the inferior and select the superior.

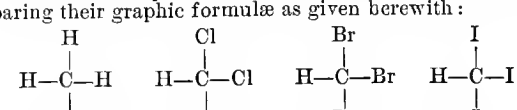
Should anyone infer from the title "Synthetic Remedies" that these remedies are wholly synthetized, they would commit a grave error. Many of these new substances could be built all the way up from their elements, but the cost of such a procedure would be so great that they would be practically excluded from general use. As found in the market they are all derived from substances chemically quite complex, by substituting desired radicals for some less desirable held within the compound. Substances once deemed valueless, or of relatively small value, have their molecules reconstructed in minor details, but in such a way that their value is very materially enhanced. This is on the principle that it costs less to remodel and finish a house already partly built, than to construct the same house *de novo*.

A number of well-known remedies, at one time derived exclusively from the vegetable world, are now built by the chemist out of what once were waste products of gas-works. This is accomplished at a cost much below that required in extracting them from plants. Salicylic acid, oil of wintergreen, and resorcin are good examples. Gaultheria procumbens and Betula lenta for years supplied the first two, and Ferula galbaniflua the last. Then salicylic acid was made from oil of wintergreen. Now oil of wintergreen is made from salicylic acid, and the acid is produced synthetically. The number of plant products for which synthetic processes are known is now quite large and is constantly increasing, but in many of them the cost is too great to make the transmutation financially profitable. This, however, is a most promising field for the future.

The vegetable alkaloids have received a large amount

of attention from chemists, but so far not with as brilliant success as might be desired. The promise, in spite of innumerable failures, is exceedingly good, and what has been done is of very great interest. Cocaine has been synthetized from ecgonine, benzoic aldehyde, and methyl iodide. When these three substances are heated together at 100° C. for ten hours it is produced. If we could but synthetize the ecgonine from some common material our triumph would be complete. As it is, our only source of ecgonine is cocaine itself. There is, therefore, no other known source of cocaine than Erythroxylon coca. A study of its decomposition products shows it to be beta-oxy-methyl-beta-pyridyl-propionic acid. Conine, the poisonous alkaloid of Conium maculatum, has been produced from allyl-pyridine by the action of metallic sodium on a boiling alcoholic solution. The allyl-pyridine is synthetically constructed from alpha-picoline and paraldehyde. The methyl, ethyl, and propyl ethers of cupreine have been produced and are said to possess the antiperiodic and antipyretic properties of quinine. Besides these, two alkaloids isomerous with quinine are likewise known. In the cupreine ethers the significant fact has been observed that their therapeutic activity is directly as their molecular weights, that of methyl being least active, of ethyl intermediate, and propyl most active. When Dr. Knorr synthetized antipyrine he thought he was on the way to quinine. On producing a substance known as phenyl-methyl-pyrazolone, from which the antipyrine was subsequently made, he thought he had secured a body that enters into the structure of quinine, and known as methyl-oxy-quinizine. Luckily for him, he had found a prize more valuable than that he sought. His experience was much like that of Columbus, who went forth in search of a new route to an already known world, but finished up by discovering a new world. He has the honor of producing a substance in every respect similar to the vegetable alkaloids, but which no plant has, so far as known, ever contained. Furfurine and thalline are two more just such remarkable bases that attest the skill of modern synthetic chemists in their imitation of the methods of organic creation.

At the very threshold of organic chemistry lie three synthetic remedies, two of which are well known to every medical man. They are chloroform, iodoform, and bromoform. It is more economical to produce these from alcohol or some alcohol derivative than to directly synthetize them from the basic nucleus of organic bodies. Their positions make them of supreme theoretical importance in connection with this subject. Marsh gas or methane (CH_4) bears the same relationship to complex organic molecules that a cell does to our bodies. From it every other organic substance is supposed to be built. It is the fire-damp of mines and one of the main constituents of illuminating gas. When a long pole is pushed to the bottom of a marsh or swamp where much organic matter is decomposing, it bubbles up and may be collected in inverted bottles of water by displacement. If this gas is mixed with chlorine and carbon dioxide, and exposed to direct sunlight, one of the products is chloroform. This substance is therefore one of the easiest to synthetize. The hydrogen of the marsh gas unites with part of the chlorine to form hydrochloric acid, while the rest of the chlorine takes its place around the carbon atoms. Where but three of the hydrogens are thus displaced the product is chloroform. The usual method of preparing this substance is by distilling dilute alcohol and chloride of lime together. It can be prepared much more economically in this way. When the hydrogen of marsh gas is replaced by iodine and bromine to the same extent, iodoform and bromoform result. In practice, however, marsh gas is not used in producing any of these substances. Their relationship to one another is very obvious on comparing their graphic formulæ as given herewith:



Marsh Gas. Chloroform. Bromoform. Iodoform.

There is an extensive series of bodies having for their molecular skeletons chains of carbon atoms, and that are known as the fatty series. Methane and its derivatives are at the beginning. A large number of the synthetic remedies, when considered chemically, belong therein. Most of them are derivable directly or indirectly from alcohol. Among them may here be mentioned ether, paraldehyde, chloral hydrate, acetic acid, acetic ether, and ethyl nitrite. Alcohol is procured commercially from the fermentation and distillation of amylaceous or saccharine substances. Its synthesis from olefiant gas by dissolving it in concentrated sulphuric acid, diluting, and distilling is easy of accomplishment, but never done to any extent. Chemically considered, it is a molecule of water in which the radical ethyl has displaced an atom of hydrogen, thus:

Water. Alcohol.

Here the symbol Et stands for C_2H_5, a group that behaves very much as an atom would. The olefiant gas used in making alcohol can itself be synthetized from sulphuretted hydrogen, bisulphide of carbon and carbon, monoxide, by passing a mixture of them over red-hot iron. As any elementary work on chemistry tells how these last gases can be prepared from their elements, it is unnecessary to follow them farther. If the second hydrogen of the water molecule is replaced by a second ethyl, we procure ether, the symbol of which may be written thus:

Sulphuric Ether.

This substitution is very easily accomplished by distilling alcohol with sulphuric acid. The acid itself takes no part in the new molecule, so that to call it sulphuric ether is wrong. It would be an easy task to trace out the synthesis of a large number of these remedies, but it would occupy more space than is alloted to this article. Those already given will answer for the fatty series, since they show the general methods pursued.

Seven new substances have lately come forward, claiming to be good anæsthetics. Some of them are intended for the production of general, and others of local, anæsthesia. The three in the second column of the list given below are used as sprays to destroy the sensitiveness of parts intended to be operated upon. Bromoform and carbon tetrachloride are being put forward as almost specifics for the abortion of whooping-cough. They are administered by inhalation, or the bromoform may be given one or two drops at a dose internally.

ANÆSTHETICS.

Bromoform, $CHBr_3$	Ethyl chloride, C_2H_5Cl
Carbon tetrachloride, CCl_4	Methyl chloride, CH_3Cl
Ethyl bromide, C_2H_5Br	Methylene chloride, CH_2Cl
Pental $(CH_3)_2$	$C.CH.CH_3$

The great majority of our new hypnotics and all of the old ones belong, chemically, within the series we are now considering. When we come to the aromatic series, we shall find thymacetin, hypnone, and hypnol, as bodies containing aromatic radicals in their structures. As hypnol contains antipyrine in its composition, it possesses many of the properties of that substance. Amylene hydrate possesses anodyne and antispasmodic qualities combined with its hypnotic. Chloralamide and chloralimide are sedative. Paraldehyde is said to aid the appetite in those who use it for producing sleep. Its great drawback is the strong odor it imparts to the breath. Sulphonal is usually slow to operate, requiring to be taken at least an hour before the time it is wanted to act. Some authorities have seriously condemned its use, while others pronounce it perfectly harmless. An anomalous feature connected with its manufacture is the fact that in Germany, whence our whole supply is derived, the government will not patent it. Owing to competition, it there

sells at the rate of forty cents per ounce. Here, where it is not made, it is patented and the price is $1.35 per ounce. "The sick of the United States are taxed ninety-five cents per ounce to pay a German a bounty his own country refuses him." This is one of the bad features of protection.

NEW HYPNOTICS.

Name.	Formula.	Dose.	Condition.	Water solubility.
Amylene hydrate	$(CH_3)_2C_2H_5COH$.	45 to 60 m.	Liquid.	Slightly.
Chloralamide	$CCl_3CH.OH.CONH_2$.	30 to 45 grs.	Crystals.	Slightly.
Chloralimide	$CCl_3CH.NH$.	6 to 10 grs.	Crystals.	Insoluble.
Methylal	$CH_2(OCH_3)_2$.	15 to 30 m.	Liquid.	Slightly.
Paraldehyde	$(OCHCH_3)_3$.	30 to 60 m.	Liquid.	Slightly.
Sulphonal	$(CH_3)_2C(SO_2C_2H_5)_2$.	20 to 40 grs.	Crystals.	Insoluble.
Tetronal	$(C_2H_5)_2C(SO_2C_2H_5)_2$.	15 to 30 grs.	Crystals.	Insoluble.
Trional	$C_2H_5.CH_3C(SO_2C_2H_5)_2$.	20 to 40 grs.	Crystals.	Insoluble.
Urethane	$CO.NH_2.OC_2H_5$.	15 to 45 grs.	Crystals.	Very soluble.
Uralium	$CCl_3CH.OH.NHCO_2.C_2H_5$.	15 to 30 grs.	Amorphous.	Insoluble.

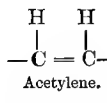
The next list embraces a number of substances having diverse therapeutic qualities, some of them being only applied externally in skin diseases. Opposite each is given its most important use. None of them contain the closed carbon rings of the aromatic series. They do not all belong, however, to the fatty series.

MISCELLANEOUS NEW REMEDIES.

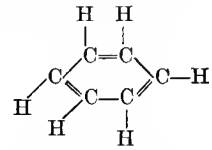
Name.	Formula.	Use.	Dose.	Condition.	Water solubility.
Allyl tribromide	$C_3H_5Br_3$.	Antiasthmatic.	2 to 5 m.	Liquid.	Insoluble.
Ethylene bromide	$C_2H_4Br_2$.	Sedative.	6 to 12 m.	Liquid.	Insoluble.
Ethyl iodide	C_2H_5I.	Antispasmodic.	3 to 5 m.	Liquid.	Insoluble.
Hydroxylamine hydrochloride	$NH_2.OH.HCl$.	Dermic.	External use.	Crystals.	Very soluble.
Iodol	C_4I_4NH.	Dermic. Alterative.	8 to 15 grs.	Powder	Insoluble.
Mercury succinimide	$(C_4H_4O_2N)_2Hg$.	Antiseptic. Alterative.	$^1/_{60}$ to $^1/_{30}$ gr.	Crystals.	Very soluble.
Piperazine	$C_4H_{10}N_2$.	Uric solvent.	10 to 15 grs.	Solid.	Very soluble.
Potassium di-thiocarbonate	K_2COS_2.	Dermic.	External use.	Powder.	Very soluble.
Sodium thiophene sulphonate	$C_4H_3S.NaSO_3$.	Dermic.	External use.	Powder.	Insoluble.

The rest of the synthetic remedies now about to be considered, all contain within their structures groups of carbon atoms in closed rings. This peculiarity of their structure was first proven by Kekule, and has since been confirmed by many new discoveries and independent facts. The knowledge of this fact has been of direct service to the student of organic chemistry, and has aided discovery to a marked degree. The source of the raw material from which they are built up is usually coal tar. The famous English metaphysician of whom Lord Byron wrote, "When Bishop Berkeley said there was no matter, he proved it was no matter what he said," had at least one kind of matter that he seemed to believe in. He spared no pains in extolling tar as a sovereign remedy in almost every ailment. Many an invalid he supplied with tar water, assuring them of its wonderful curative power. As a vestige of his propaganda we find it still endorsed in some quarters as a popular remedy in colds. Previous to this time superstitious people found its greatest use in decorating doors, walls, and fences with the sign of the cross. They believed that this sign, so made, kept devils away, stayed plagues, and checked epidemics of disease. Its black color and adhesive quality made it an admirable pigment for this purpose. Could the good bishop of Cloyne now see the wonderful array of new synthetic remedies that have lately been produced from it, he would most likely be heard to say, "I told you so!" Not only do we use its products to sooth pain, check fever, subdue inflammations, and heal wounds, but we have drawn from it a wonderful array of brilliant colors with which to decorate our homes and persons.

The study of the chemical relations of the synthetic remedies derived from coal tar is one of the most fascinating chapters in modern science. To trace the successive steps by which substances almost wholly unlike in properties are transmuted into each other, seems almost like a fairy tale. Some slight appreciation of the subject can be acquired by following the route leading toward some of the simplest. As methane (*i.e.*, marsh gas) is the commencing nucleus of the fatty series, so benzene (*i.e.*, benzol) is the point of initiation of the aromatic series. Either can be transmuted into the other. When methane is exposed to a strong heat, part of its hydrogen is driven off and acetylene formed. Part of the acetylene instantly coalesces into triple-sized molecules that form the benzene ring. A glance at the graphic formula of acetylene and then at benzene, will show that the latter is merely three of the former united together.

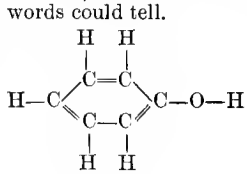


Acetylene.

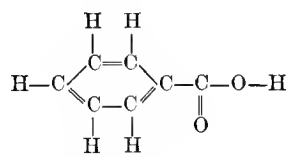


Benzene.

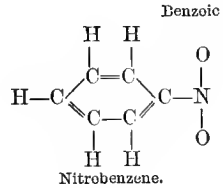
By a single act of synthesis for each there are three substances of interest to medical men producible from benzene. They are carbolic acid, benzoic acid, and nitrobenzene. The latter has been extensively used as an adulterant of oil of bitter almonds, which it resembles. The true oil is mainly composed of benzoic aldehyde and is produced synthetically on a large scale. Carbolic acid results when oxygen is passed into boiling benzene in the presence of aluminium chloride. When benzene is oxidized with plumbic oxide and sulphuric acid, benzoic acid results. When fuming nitric acid acts on benzene, nitrobenzene is the product. The following graphic formulæ of these three bodies, when compared with that of benzene, will show how close of kin they are, better than words could tell.



Carbolic acid.

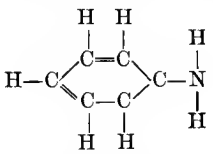


Benzoic acid.

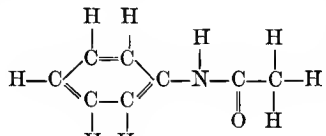


Nitrobenzene.

It is a well-known fact that hydrogen immediately on its release from combination, and before it has had time to recombine even into its own gaseous molecules, is much more active than at any other time. It is then said to be nascent. If such hydrogen is allowed to act on nitrobenzene, it produces aniline oil. The oxygen is removed to form water and the nitrogen takes two atoms of hydrogen into their places. The nascent hydrogen is procured by acting on zinc or iron with a dilute mineral acid. If the aniline oil so procured is boiled for about forty-eight hours with strong acetic acid, one of the products is acetanilid, chemically known as phenylacetimid. This last body is the first important antipyretic ever produced synthetically, and so few are the steps necessary to reach it that it is the cheapest, and by many deemed the best, yet given to the world. As "antifebrine" a fictitious price has been placed upon it, but "a rose by any other name will smell as sweet." A comparison of the graphic formulæ of these two with that of nitrobenzene will show clearly the steps of change.

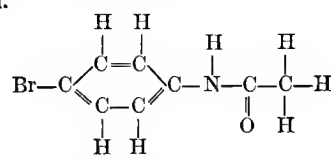


Aniline oil.



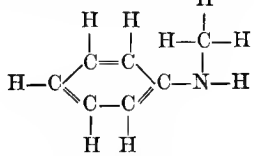
Acetanilid.

If bromine is passed into a solution of acetanilid, parabromacetanilid results. This body has been put upon the market as a good antipyritic, antiseptic, and nervine, under the names of antisepsine and asepsine. It has not met with a great deal of success, and is now seldom heard from.

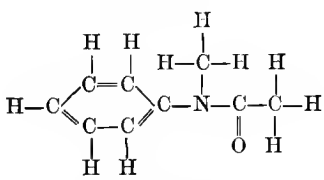


Antisepsine.

Exalgine, or methylacetanilid, was first described by Hoffman, the German chemist, in 1874. It only differs from acetanilid in that the hydrogen atom united with the nitrogen is removed to give place to a methyl group. The route taken in its construction is somewhat different from that followed in the case of acetanilid. The aniline oil, instead of being acted upon by acetic acid, is caused to react with methyl chloride, thus forming methyl aniline. The methyl aniline thus formed when heated with acetyl-chloride gives exalgine.



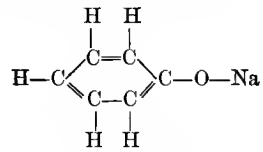
Methyl aniline.



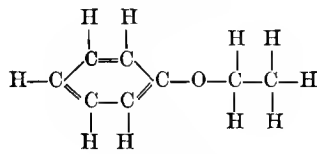
Exalgine.

Exalgine is very largely used as an analgesic. Some authors have pronounced it superior to all others for removing pain, while others have condemned it as dangerous. It has been successfully used for chorea, and locally, on burns, to allay pain.

At present one of the most extensively used new synthetic remedies is phenacetine. To reach its structure more steps must be taken than for any yet given. It rejoices in the long chemical name of para-acet-phenethidine. It is well for those not familiar with the nomenclature of organic chemistry to remember that every syllable in such titles tells something about the structure. In this one the "para" tells that the two added groups are opposite to each other, or at the farthest distance from each other in the phenyl radical which the "phen" stands for. The "acet" represents the acetic group and the "eth" the ethylic. The "id" stands for the ammonia radical that has had part of its hydrogen replaced. The synthesis of this body begins with carbolic acid. When this pseudo-acid is acted upon by strong soda lye the product is sodium phenate. When equal volumes of sulphuric acid and alcohol are mixed and cooled, the mixture neutralized with caustic soda and evaporated till crystals appear, and the liquid poured from the crystals into a strong solution of sodium phenate heated under heavy pressure to 150° C., phenctole results. The changes that occur in these reactions can be seen by comparing sodium phenate and phenetole's graphic formulæ with that of carbolic acid before given.

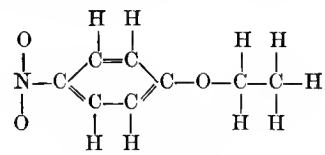


Sodium phenate.

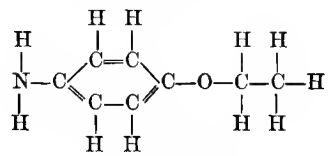


Phenetole.

When phenetole and fuming nitric acid are brought together union occurs, and the product is para-nitrophenetole. This reaction is the same as that which gives nitrobenzene from benzene. The next step on the way to phenacetine is the same as that from nitrobenzene to aniline oil. The oxygen of the "nitro" radical is removed by nascent hydrogen, procured, as already described, by the action of a mineral acid on zinc or iron. This gives para-phenethidine. A comparison of the graphic formulæ of these two bodies will show that they bear exactly the same relationship to each other as nitrobenzene bears to aniline.



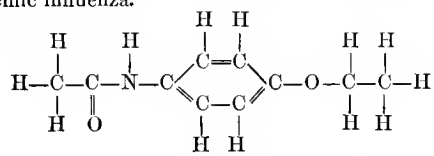
Para-nitro-phenetole.



Para-phenethidine.

When para-phenethidine is purified by successive recrystallizations, heated with glacial acetic acid for some hours, and the products of this reaction recrystallized from water, phenacetine is one of the substances produced. This is one of the best remedies we have in aborting attacks of whooping-cough and in incontinence.

of urine. Mixed with salol it is admirable in headaches of a neuralgic type. It has proven of great service in epidemic influenza.



Phenacetine.

Most of the ring grouped medical compounds possess antiseptic qualities. Some are decidedly bacteriacidal and have been put upon the market for use by the surgeon and dermatologist. The cresols are particularly interesting because of their freedom from toxic qualities and their great antiseptic power. They are many times more active than carbolic acid, and yet eight or ten times less poisonous. Preparations containing them have been marketed under the names creolin, lysol, and solveol. Chemically there are three isomeric bodies bearing the name cresol, and all are highly antiseptic. Of bodies containing iodine, and therefore believed to possess some of the qualities of iodoform, while free from its objectionable odor, we have aristol, europhen, losophane, picrol, and sozoiodol. Two aniline dyes have proven of great value in this field, some excellent authorities going so far as to claim for them the power of curing carcinoma. One is a blue and the other a yellow. They are known as pyoctanins.

Synthetic External Antiseptics.

Anthrarobin, $C_6H_4.C.OH.C_6H_2(OH)_2CH.$
Aristol, $C_6H_2(C_3H_7.CH_3)_2C.OI.$
Cresols (3), $C_6H_4.CH_3.OH.$
Diaphtherin, $C_6H_4(HO.C_6H_9.NH.O)_2SO_2.$
Europhen, $(C_6H_3O.C_4H_9.CH_3)_2HI.$
Gallacetophenone, $C_6H_2(OH)_3.COCH_3.$
Losophane, $C_6H.I_3.OH.CH_3.$
Naphthols (2), $C_{10}H_7.OH.$
Oxynaphthoic Acid (a), $C_{11}H_8O_3.$
Picrol, $C_6HI.(OH)_2.SO_3K.$
Pyoctanin (blue), $C_{19}H_{12}(CH_3)_5N_3.$
Pyoctanin (yellow), $(C_6H_4.N(CH_3)_2)_2C.NH.$
Sozal, $(C_6H_4.OH.SO_2)_6Al_2.$
Sozoiodol, $C_6H_2I_2.OH.SO_3H.$
Sulphaminol, $C_{10}H_3.OH.S.NH.$
Xylene, $C_6H_4(CH_3)_2.$

The following four are said to be good antiseptics, whether administered internally or applied externally. The first and fourth have been extolled as cures for consumption. The third has anodyne, tonic, and antipyretic properties :

Synthetic Internal Disinfectants.

Name.	Formula.	Dose.	Condition.	Water Solubility.
Benzosol	$C_6H_4.OCH_3.OC.O.C_6H_5$	4 to 12 grs.	Powder.	Insoluble.
Bromol	$C_6H_2Br_3.OH$	$^1/_{10}$ to $^1/_3$ gr.	Crystal.	Insoluble.
Ichthyol	$C_{28}H_{36}S_3O_6(NH_4)_2$	5 to 20 m.	Liquid.	Very soluble.
Styracol	$C_6H_5.(CH.)_2CO_2.C_6H_4OCH_3$	1 to 2 grs.	Crystal.	Insoluble.

The most important and most numerous of the new synthetic remedies are the antipyretics. They all possess some antiseptic power and the majority of them can be used as analgesics. The power that a few of the best known have in subduing pain is quite remarkable. The greatness of the boon they have thus conferred upon us cannot be over-estimated. Thousands are thereby saved from contracting the morphine habit and becoming moral wrecks. The great solubility of antipyrine in water gives it a decided advantage over its rivals, and the fact that it has in a remarkable degree the power of checking hemorrhage is likewise in its favor. Cases of epistaxis that nothing seemed able to arrest will instantly cease on injecting a twenty per cent. solution into the nares, and that, too, without forming an annoying clot or giving the patient any discomfort. The following list comprises such antipyretics as have gained notoriety up to the present time :

Synthetic Antipyretics.

Name.	Formula.	Dose.	Condition.	Water Solubility.
Acetanilid	$C_6H_5.NH.CH_3CO$	3 to 8 grs.	Powder.	Slightly.
Acetyl-amidophenol	$C_{18}H_9NO_4$	3 to 8 grs.	Powder.	Slightly.
Agathin	$C_6H_4.OH.CH.NH.CH_3C_6H_5$	3 to 8 grs.	Solid.	Insoluble.
Antipyrine	$C_6H_5N.CO.CH.NCH_3.CCH_3$	15 to 30 grs.	Powder.	Very soluble.
Antisepsin	$C_6H_4Br.NH.C_2H_3O$	3 to 10 grs.	Crystal.	Insoluble.
Asaprol	$(C_{10}H_8SO_3.HO)_2Ca+3H_2O$	15 to 60 grs.	Powder.	Very soluble.
Benzanilide	$C_6H_5NH.CO.C_6H_5$	15 to 45 grs.	Crystal.	Insoluble.
Benzo-naphthol	$C_6H_5.CO_2C_{10}H_7$	4 to 10 grs.	Powder.	Insoluble.
Betol	$C_6H_4.OH.CO.O.C_{10}H_7$	5 to 6 grs.	Powder.	Insoluble.
Chinoline	C_9H_7N	5 to 20 m.	Liquid.	Insoluble.
Cresalols (3)	$C_6H_4OH.CO.C_6H_4.CH_3$	10 to 20 grs.	Powder.	Insoluble.
Diuretin	$C_6H_4.OH.COONa.C_7H_7Na.N_4O_2$	15 to 20 grs.	Powder.	Very soluble.
Eugenol	$C_{10}H_{12}O_2$	4 to 15 m.	Liquid.	Insoluble
Euphorin	$C_6H_5.NH.COO.C_2H_5$	3 to 8 grs.	Powder.	Insoluble.
Exalgine	$C_6H_5N.CH_3.CH_3.CO$	1 to 5 grs.	Powder.	Slightly.
Guaiacol-salol	$C_{19}H_{12}O_4$	3 to 4 grs.	Powder.	Insoluble.
Hydracetine	$C_6H_5.HN.NH.CH_3.CO$	$^1/_6$ to 1 gr.	Crystal.	Slightly.
Hydroquinone	$C_6H_4(OH)_2$	10 to 50 grs.	Crystal.	Soluble.
Iodopyrine	$C_6H_4IN.CO.CH.NCH_3.CCH_3$	8 to 24 grs.	Crystal.	Slightly.
Methacetine	$C_6H_4OCH_3.NH.CH_3CO$	1 to 3 grs.	Crystal.	Insoluble.
Methylene blue	$(C_6H_3N[CH_3]_2Cl)_2NS.$	1 to 8 grs.	Crystal.	Slightly.
Ortho-amid salicylic acid	$C_6H_3.HO.COOH.NH_2$	6 to 10 grs.	Powder.	Insoluble.
Phenacetine	$C_6H_4.OC_2H_5.NH.CH_3CO$	4 to 12 grs.	Powder.	Insoluble.
Phenocoll hydrochloride	$C_6H_4.OC_2H_5.NH.CO.CH_2NH_2HCl$	7 to 15 grs.	Powder.	Soluble.
Resorcin	$C_6H_4(OH)_2$	1 to 15 grs.	Crystals.	Very soluble.
Salicylamide	$C_6H_4.OH.CO.NH_2$	3 to 5 grs.	Crystals.	Slightly.
Salipyrine	$C_{11}H_{12}N_2O.C_7H_8O_2$	10 to 15 grs.	Powder.	Insoluble.
Salol	$C_6H_4.OH.COO.C_6H_5$	5 to 20 grs.	Powder.	Insoluble.
Salophen	$C_6H_4.OH.COO.C_6H_4.NH.COCH_3$	60 to 90 grs.	Powder.	Insoluble.
Sodium di-thiosalicylate	$(C_6H_3S.NaO_2C.OH)_2$	1 to 3 grs.	Powder.	Very soluble.
Sodium paracresotate	$C_6H_3.CH_3.OH.COONa$	15 to 30 grs.	Crystal.	Slightly.
Sodium salicyl-sulphonate	$C_6H_3HO.COOH.SO_3Na$	6 to 10 grs.	Crystal.	Very soluble.
Thalline tartrate	$C_{10}H_{12}NO.C_4H_6O_6$	2 to 8 grs.	Crystal.	Soluble.
Toluene	$(C_6H_5)_2CH_2$	3 to 7 grs.	Crystal.	Insoluble.

The following three bodies have distinct hypnotic qualities that entitle them to a separate classification, although they possess, in a marked degree, the antipyretic and analgesic powers of the members of the last group. Acetanilid and phenacetine have so quieting an effect on most persons who take them that they might almost have been placed in this group. Many a sick and restless child has been put to sleep by a dose of acetanilid as effectually as it could have been by paregoric.

SYNTHETIC HYPNOTIC ANALGESICS.

Name.	Formula.	Dose.	Condition.	Water solubility.
Hypnal	$C_6H_5(CH_3)_2C_3HN_2O.CCl_3CHO$	10 to 15 grs.	Crystal.	Slightly.
Hypnone	$C_6H_5.COCH_3$	1 to 3 m.	Liquid.	Insoluble.
Thymacetine	$C_6H_2.CH_3.C_3H_7.OC_2H_5.NH.C_2H_3O$	5 to 15 grs.	Crystal.	Slightly.

The next list contains the new sweetening substances that have been such a boon to diabetic patients who are not permitted to use sugar. The sodium salts of the last two are quite soluble in water and sweeter than themselves.

SYNTHETIC SUGAR SUBSTITUTES.

Name.	Formula.	Dose.	Condition.	Water solubility.
Dulcin	$C_6H_4.OC_2H_5.NH_2.NH.CO$	3 to 10 grs.	Powder.	Soluble.
Saccharin	$C_6H_4.CO.SO_2.NH$	½ to 8 grs.	Powder.	Slightly.
Saccharin amide	$C_6H_4.CO.SO_2.NH_2$	½ to 8 grs.	Powder.	Slightly.

The final list contains substances, each of which has properties unlike any of our groups and unlike each other.

Fluorescine is a product of the union of resorcin and phthalein, having the remarkable power of selecting and staining diseased corneal tissue, thus being a valuable means of diagnosis in the hands of the ophthalmologist. Orexine hydrochloride has been used for the purpose of promoting the appetite, especially of tuberculous patients. It acts much as capsicum would. Pyridine is a cardiac stimulant and antiasthmatic remedy that can be used by the mouth or by inhalation. Terpin hydrate is an expectorant and diuretic. It is a product of the interaction of turpentine, alcohol, and nitric acid.

MISCELLANEOUS SYNTHETIC SUBSTANCES.

Name.	Formula.	Dose.	Condition.	Water solubility.
Fluorescin	$(C_6H_3[OH]_2)_2(CO)_2$	0.	Crystals.	Soluble.
Orexine hydrochloride	$C_6H_4.NCH.CH_2N.C_6H_5HCl$	4 to 8 grs.	Crystals.	Very soluble.
Pyridine	C_5H_5N	3 to 4 m.	Liquid.	Very soluble.
Terpin hydrate	$C_{10}H_{16}(OH_2)_2$	3 to 15 grs.	Crystals.	Insoluble.

When the United States Pharmacopœial Convention met in Washington in May, 1890, one of the most serious questions that body had to consider was the admission of synthetic remedies into the revised edition of our national standard text-book of materia medica. The Committee of Revision was instructed to exclude all patented substances, on the ground that, however definite they may be as chemical bodies when pure, no one could be certain of their composition while but one firm had the right of production. In proof of this fact was cited the case of saccharin, that different chemical observers had found ranging in sweetening power all the way from 130 to 330 times that of sugar. The testimony of Professor Remsen, that it was often adulterated to half its proper strength, was also referred to. Now its manufacturers have come out with what they claim to be an article of double the strength of that formerly made by them. For the revisors to fix a standard of say 200 times the sweetness of sugar, would be to lay pharmacists liable to prosecution for deviating from that standard, when in fact the manufacturer might alone be responsible. The maker of any patented substance can, upon a mere whim, change it as much or as often as he chooses, and no one can interfere. It is theirs, and they can do as they see fit with it. In fact they are not even compelled to supply that article at all. Medical men and pharmacists are totally at their mercy. They can add or subtract what they choose and when they choose. The one thing, of all others, that makes it possible for a science of medicine to exist, viz., uniformity, is in no such case assured, and is in fact frequently lacking. When antipyrine, phenacetine, exalgine, iodol, hypnal, sulphonal, aristol, and a host more of these remedies are used, we are compelled to trust to the honor of the manufacturer as to their purity. Many of them have been found adulterated and the blame cast upon the pharmacist who supplied the same. But why blame the pharmacist? What evidence can anyone get that the work of adulteration was not that of the manufacturer? In all other kinds of goods the law can compel purity. The man who sells adulterated goods can be punished. When there is no competition the only standard we can have is that the manufacturer may see fit to make. It might be said that he would naturally desire to keep up the standard of his goods, and would therefore not resort to such methods. In answer to this stands the fact that one manufacturer has practically confessed that he did resort to adulteration to the extent of fifty per cent.

Since acetanilid is not patented it will be admitted to the Pharmacopœia. One enterprising firm finding itself unable to secure a patent on so well-known a substance, resorted to the device of rechristening it "antifebrin," and thus gaining a perpetual patent on the name. This enables them to demand a fabulous price from all sick people whose physicians know no better than to prescribe it under their name. Various combinations of this substance with others are being extensively sold under copyrighted names, the most popular of which begin with the prefix "anti." Samples are freely distributed among medical men. Advertisements appear in nearly every medical journal. Even journals supported by medical societies and that ought to be free to reject such advertisements, cater to such trade. Such mixtures have been recommended in apparently grave scientific papers before medical societies. Their manufacturers describe them as coal-tar products of certain chemical series. Indefinite formulæ of these series are given, but never a definite one of any kind. They are neither more nor less than secret remedies, such as the sarsaparillas and safe cures of the drug stores. Since tens of thousands of dollars are spent annually in advertising them among medical men, it is certain that, in defiance of ethics and in

defiance of the necessities of science, they are being, not slightly, but to an enormous extent, prescribed. Every physician who uses such preparations is robbing his patients, himself, and his profession of money, dignity, and progress. The iodide of potassium in a patent sarsaparilla helps many cases of disease where that remedy is indicated. Mixtures of acetanilid with bicarbonate of soda and caffeine, are, no doubt, excellent succedaneæ for morphine, but when administered under copyrighted names and in ignorance of their true natures, wherein do they differ from the worst patent-medicine frauds? They do differ in one thing. These pretended coal-tar synthetic remedies are sent out enveloped in a false claim as to their very natures, while the well-known cure-alls are honest in their secrecy. Why, then, do medical men patronize the worst and indignantly reject the best? Let no medical man prescribe a remedy that claims to be synthetic, and yet will effervesce on the addition of a dilute acid. It can safely be set aside as something other than it is represented to be.

Power is power. Of course this is a truism well known to all. In its application, however, it is very frequently overlooked. In using synthetic or any other remedies, it is wise to remember that all forms of power can be either injurious or beneficial according to when, where, and how they are used. If anyone is waiting for a perfectly harmless remedy that is therapeutically potent, he is likely to wait in vain. Enterprising manufacturers, when introducing their new products, invariably tell us that they are free from ill effects. Such statements should always be taken *cum grano salis*. Rivals soon discover their ill effects and exaggerate them, thus playing upon the fears of the prescriber. Great allowances should likewise be made on what these say. Always anticipate some ill effects, and there will not be incessant disappointment. From irrational laudation to disgust and rejection are but a step. No surgeon refuses to use a keen-edged bistoury because it has done harm in unskilled hands. He should not lay aside a useful drug for a similar reason.

It is a singular fact, that although chemists have synthetically produced scores of antipyretics, analgesics, hypnotics, and antiseptics, no new cathartics like that which gives croton-oil or elaterin their qualities have been produced this way. Nor have we heard of any powerful anthelmintics like santonine, mydriatics like atropine, oxytocics like ergotin, or emetics like emetine. The synthesis of a local anæsthetic, like cocaine, would be of great value. It would not be surprising if cocaine itself should prove to be the first. One important step has already been successfully taken. To find one body having valuable new therapeutic qualities, is usually to be on the way toward the discovery of more with the same quality. An ortho preparation among the derivatives of benzene suggests a meta and a para of the same kind with similar qualities. A methyl derivative suggests an ethyl or propyl as good ones to try. In quinoline derivatives an alpha suggests a beta. When a prospector, in the mountains, strikes a vein of gold, he usually knows how to follow, even though it appears to run out. Experience teaches him not to give up immediately because the "color" disappears. He is more likely to be successful in following a lead that begun well than he would be should he try to discover a totally new one in a different region. It is the same in synthetically producing new remedies. No one can predict what will come next after exhausting a certain type, but once begin on a new, and we may expect a number of additions from the same quarter. *Robert G. Eccles.*

SYPHILIS. Syphilis and the Columbian Discoveries.—Interest has been revived in the questions relating to the supposed American origin of syphilis by fresh studies of original documents, and by recent discoveries in different portions of the continent of bones supposed to exhibit changes due to the disease. Papers touching on the theme originally so well elucidated by Joseph Jones, of New Orleans, have appeared from the pen of Bruehl and others, throwing further light upon both sides of the problem. The writings of Sahagun, Torquemada, Roman, Mendieta, Pane, and others have been found to show, as to New Spain, that the bodies of those affected with syphilis were interred, as distinguished from those dead of other disorders, which were cremated; that the infected were not deemed fit for religious sacrifices; that they were not represented at the festivals; and that the disease was counted a punishment sent from the gods for the non-performance of religious rites and other offences. The Mexicans not only recognized the connection between the earliest and later manifestations of the disorder, but distinguished between several types of the former, understanding also its remedial treatment far better than the Spaniards, even seeking thermal resorts for the purpose of securing relief. In seventeen Indian dialects, each of which has a primitive and native term for designating the disease, none of the terms thus employed suggest confrontation with a new malady, although soon after contact with the whites the natives were compelled to apply new names to many novel objects with which they were to become familiar. These new names either bear witness to the impression on their ears made by the speech of the Castilians, or describe some prominent feature of the object to be newly named, a rule distinctly observed by them in the case of diseases known to have been imported from Europe to America, as for example, measles and small-pox. The singular confusion existing in the Mexican language of the sixteenth century, of the terms employed to indicate ideas of power, divinity, and the special disease here under discussion, possesses an interest in view of the fact that this is recognized in the dialects of Quechua and Aymeras, three hundred years before Pizarro conquered the capital of the Incas.

With a view to determining the nature of the osseous changes in bones of the class commonly cited as proofs of the existence of a prehistoric syphilis, the author selected from parts of a skeleton exhumed from a pre-historic burial site on the Animas River, Col., two tibiæ, one especially and characteristically deformed, which were submitted for examination to Dr. T. M. Prudden, of the laboratory of the College of Physicians and Surgeons of New York. The shaft of the left tibia, he reported, is bowed considerably forward at its middle and lower portions. The shaft, which is nearly cylindrical, is everywhere greatly increased in thickness, measuring from 4 to 4.5 centimetres in diameter in all parts except at the lower end, where it is slightly smaller. The whole bone is very light in weight.

"About the articular end, at the knee-joint, the bone presents erosions, irregular losses of substance, and numerous larger and smaller bony outgrowths — the latter being most marked about the front of the joint, and especially about the seat of attachment of the ligamentum patellæ. The fibular articular surface is completely destroyed. The entire surface of the shaft is roughened and porous, and beset here and there, especially along the lines of tendinous attachment, with larger and smaller rows and masses of the delicate bony outgrowths called osteophytes. These osteophytes are especially prominent along the lateral and posterior aspects of the shaft. Branching grooves in the surface of the bone, and delicate projecting bony plates and spiculæ and ridges, contribute to the roughness of the shaft.

"Transverse sections of the shaft of this bone at its middle third show that the bone, which from the outside appears to be largely hypertrophied, is a mere fragile cylindrical shell, the peripheral compact bone being almost everywhere thin and uneven, the bulk of the shaft consisting almost wholly of irregular cancellous or spongy tissue.

"The more delicate central trabeculæ of the cancellous tissue, which apparently nearly or completely filled the narrow cavity, have, except in a few places, largely disintegrated and fallen out with the lapse of time.

"Along many parts of the bone the cancellous tissue pierces the shell of compact bone—which, though very thin in general, encloses the shaft—and becomes contiuuous with the osteophytic outgrowths on the surface.

"The microscopical examination of the trabeculæ of the cancellous tissue in both bones, shows the usual appearance of such tissue, but the irregularity and apparent aimlessness of their grouping and arrangement indicate their formation under the influence of a chronic inflammatory process. Microscopical examination of the osteophytes exhibits irregular grouping and relative posi-

Fig. 596.—Tibia Exhibiting Osseous Changes; from a pre-historic burial site in Colorado.

tions of the bone cells and bone lamellæ, which is usually associated with inflammatory structures.

"The more compact bone-tissue from various places in the shafts of both bones shows the utmost irregularity in the arrangement, size, and direction of the Haversian canals and their surrounding lamellæ."

He reported that it was evident that these were the bones of an adult who for a long time had been the victim of an extensive chronic bone disease in both legs, with a probable involvement of the left knee. This disease was so extensive and prolonged that it had led to the nearly complete making over of the shafts of both tibiæ.

Under the influence of the inflammatory process the old bone was bit by bit absorbed, new bone being in greater or less degree formed near by to take its place. The new-formed bone has been only here and there developed in the proper amounts, situations, and relationships.

Morphologically, the character and extent of the lesions in these bones were perfectly clear. There was no evidence whatsoever that there had been either caries or necrosis. There had been, so far as the bones show, simply such a general rarefying and formative osteitis with formative periostitis, as to produce the condition often described as spongy hyperostosis. There was no evidence whatsoever of the presence, at any time, of the more common and typical circumscribed nodular or gummatous lesions, which are alone characteristic of syphilis of the bones. There were none of those circumscribed local losses of substance, associated with more or less localized sclerosis, which speak for the former presence of gummata. On the other hand, there was a more diffuse and general inflammation of the bone and periosteum, which, as is well known, not infrequently occurs in the tibia, and which is believed to be due to syphilitic infection. But even in this form of syphilitic bone lesion, the sclerotic rather than the rarefying character in the inflammation, as is the case here, is apt to prevail. In brief, there is no morphological evidence to justify a belief in their syphilitic character.

Admitting that among the bones exhumed in the northern part of the American continent, and found in the various collections of this country, there may be some which actually exhibit unmistakable lesions of syphilis, the last problem prescribed for solution is: Are any of these bones not merely syphilitic but unquestionably pre-historic? Are they parts of the skeletons of North American Indians or of the whites mingled with the latter in the confusion resulting from race admixture in war, captivity, and many common enterprises? Are they, in point of fact, the bones of individuals dead before the first of the Spaniards set foot on the soil of San Salvador in 1496? The conjecture that a people once dwelt on this soil of some pretension to civilization, building temples and cities comparable to those found in what we call the older world, has been dissipated. The artificial mounds and stone dwellings, numbering thousands, some of very small and some of imposing size, and scattered throughout the country, were once thought to be the work of an ancient race of people commonly called the "Mound-builders" and the "Cliff-dwellers," who were cited as a people showing evidence of an ancient civilization of no mean order and no common condition of culture. The bones which have been found in many of these mounds and other places of sepulture, with the so-called works of art which these tombs contain, have been regarded as the remains of these primitive peoples.

These views have, within a decade, been shown to have a broader basis in the imagination than in tangible fact. From about the middle part of the Pleistocene period to the epoch of the first advent of the whites to the American coast, the history of man in America is seen to be the history of his slow and feeble evolution from a lower to a higher advancement in the Stone age. The best product of this process of evolution was reached by the North American Indian when he first looked seaward upon the sails of the Spanish fleet. There had been nothing superior to him before; and it is a question whether anything better has been since produced by this process of evolution from his race. He built no cities; he carved no vases; his work in metals was of the crudest sort. He and his fathers, his inferiors in culture, builded these mounds for sepulture and other purposes, sometimes as the foundation for commmunal dwellings. In some por-

tions of the southwestern parts of the country, where there is little vegetation and the plains are arid, he and his fathers excavated lodgings in the cliffs that hemmed in the cañons, or constructed them of the loose rocks that were easily separated from the walls of stone on either hand. But all the mounds are not pre-historic, and the same may be said of the excavated cliff dwellings. Even of the pre-historic mounds, some have been occupied in our own day, and some have been used for the interment of bones of individuals dead long after the admixture of the white and red races upon our soil. Of the glass beads, the tools and ornaments of copper, and other articles found in them suggestive of contemporaneous interment with the human bodies, many were manufactured by the whites and furnished to the Indians in the way of barter for peltries. It is also of importance to note that, even within the mounds which are unquestionably of pre-historic structure and which undoubtedly at the first contained only the bones of a pre-historic race, there have been repeated intrusions, and these intrusive interments have resulted in depositing in such mounds, not merely bones of later generations surviving the Columbiau advent, but, indeed, large bundles of such bones, some of them apparently collected from the most miscellaneous sources.

The wide door to confusion opened by the complete recognition of facts of this character cannot be ignored. It furnishes a possibility for errors which it would be difficult to number and impossible to overestimate.

In order to demonstrate, in the case of bones obtained from any mound or burial-place of the cave-dwellers in North America, some of which exhibit evidences of syphilitic lesions of a suggestive or even unmistakable character, that the latter are proofs of a pre-Columbian prevalence of the disease, it is absolutely necessary to prove beyond question: first, that such mound or burial-place was pre-historic in construction; second, that such contained bones were interred at a pre-historic period; third, and lastly, that after such burial there had been neither intrusive interment of bones nor other disturbance of mortuary relics after their first deposit.

Chancres upon the Person of Individuals Previously Infected with Syphilis.—The occurrence of second attacks of syphilis is a possibility denied by some authors, but illustrated by cases carefully collated by Hutchinson, Diday, Koebner, Gascoyne, Taylor, Malherbe, and others. The most of these cases, when carefully examined, are to be recognized as the odd results of a re-awakening of morbid activity in the tissue of an individual previously infected. Persons thus immune against reinfection de novo, actually exhibit the evidences of exposure to syphilitic sores with results that may be classed as follows:

1. Genital lesions appear of the type of the so-called soft chancre (*chancrelle, chancre mou*, Einfacher Schanker, etc.). It cannot be demonstrated to-day in all cases that these lesions are absolutely identical with the soft chancre, but only that they strongly resemble the latter. These pseudo-chancres have no induration at the base; they secrete a puriform mucoid secretion; they are circular, sharply defined, clean-cut as to edge; they are unaccompanied by any characteristic sclerosis. It can be demonstrated by confrontation that these special lesions result from contamination of an undoubtedly syphilitic individual with the secretion furnished by mucous patches, condylomata, or indurated scleroses of persons no less certainly syphilitic. It is noticeable, however, that for the most part these sores are unaccompanied by the suppurating bubo, which so often complicates the soft chancre; and after healing, they do not appear to exert a constitutional effect upon the subject of the malady.

2. Typical initial scleroses appear with and without (usually the latter) the characteristic enlargement of the glands in the vicinity of the sore. Here the previously infected person is commonly a veteran of syphilis, having suffered a decade of years or more before the second exposure to the same virus. Even the large dense sclerosis may result which presents the most formidable picture in some cases of primary syphilis, with so slight an effect upon the adjacent lymphatics that the most expert are surprised at the absence of such symptoms. When this complication exists there may be a slight lymphangitis leading from the site of infection to glands that are very little influenced by the process. These scleroses rarely break down to ulcerations or gangrene. They are readily effaceable by the administration of mercury internally, and are followed by no consequences as respects the constitutional condition.

3. Typical initial scleroses occur, small or large, single or multiple, usually in persons not many years separated from the infection date of syphilis, sometimes but a few months, at other times one or two years so removed. These slowly or rapidly ulcerate, occasionally breaking down into really formidable losses of tissue, behind the corona glandis in men, about the hood of the clitoris or the meatus urinarius in women, the picture presented rapidly taking on the characteristic appearance of tertiary gummatous ulceration, with dense inflammatory base. These, at first of purely local significance, are shifted speedily to the point of production of the syphiloma in the subject still apt for the manifestations of constitutional syphilis.

The Destruction of the Initial Sclerosis by Cauterization or Excision is Powerless to Prevent the Occurrence of General Syphilis.—A careful survey of the later attempts to prevent the occurrence of general syphilis by the most radical measures (erasion; excision; destruction by caustics or cautery; and amputation of the entire tissue on which the chancre is seated, *e.g.*, prepuce, digit, etc.), demonstrates the futility of all. Even with the complete simultaneous removal of all enlarged glands in the vicinity of the chancre, the result is the same. The most modern of methods, and the most exhaustive of studies, have not as yet succeeded in shaking the old dictum, that every true chancre means a syphilis that follows: and every case of acquired syphilis acknowledges a chancre as its initial lesion. There are in fact few infective diseases that can be jugulated. The lymphatics are not the sole avenues by which the syphilitic virus is conveyed from its portal to any given peripheral point of the body. The failure of the tumid and indurated glands to entrap the bacilli or their toxine, is demonstrated in almost every classically developed case. Inasmuch, therefore, as cauterization of the chancre may be followed by a graver sclerosis, it is wisest to treat these local lesions by the methods proven satisfactory in all local infections, whether coccogenic or bacillogenic in origin. Absolute cleanliness, antisepsis, and unirritating dressings are indicated in all cases.

The Evolution of Syphilis Studied without Regard to the Artificial "Periods" of the French School. — Between the moment of infection and the earliest appearance of a chancre to the unaided eye, there is usually a delay of from fifteen to thirty-five or forty days, a period of twenty-one days for the average of cases. This is usually called the first incubation. Terms of this sort embody, however, the confession of an ignorance that is in part dissipated on any careful examination of the results of a successful culture in an artificial medium of micro-organisms, reproducing themselves in colonies, for example, in gelatine, or agar-agar. There is then apparent neither an incubation, a "hatching," a delay, nor an arrest. If our methods were without flaw, we should be able to detect the movement toward general infection from its very first to its completed step.

In an attempt, therefore, to study the evolution of syphilis as it is actually wrought, questions of time, the crude hypothesis of an incubation, and all really artificial distinctions, should be, for the purposes of critical investigation, assigned a true and not a fictitious value.

In the article on Syphilis, in this work, attention has already been drawn to the historical and interesting fact, that by the late eminent Philip Ricord, the evolution of syphilis was divided into three stages, the primary, the secondary, and the tertiary. The primary included the

symptoms concerning the chancre and its accompanying multiganglionic adenopathy. The secondary period included the symptoms displayed during the succeeding term, in which systemic infection occurred, with usually symmetrical and superficial cutaneous and other manifestations. This was loosely estimated at about one year in duration. Lastly, following this stage of efflorescence, came the tertiary period, that in which the deeper structures of the body are involved; that in which the disease commonly ceases to be transmissible, in which it may produce its most destructive effects, or pass into a complete innocuousness and decline. The influence of this doctrine of periods has been incalculably great and valuable. It once marked a revolution in the history, in the study, and in the treatment of the disease. It has dominated the minds of the medical men of all lands since it was first completely grasped by the intellect of its master.

But it has served its day. To thoroughly grasp the problems of syphilis, it is now needful, for the time being, to emancipate the mind wholly from the ingenious suggestiveness of this doctrine. It must be clearly seen to be nothing but an artificial device for classifying in a clumsy way the clinical phenomena of the disease.

As a matter of fact, there is no line of demarcation between the successive phenomena of syphilis as they appear in the evolution of the disease in any given case. From the moment when infection has been wrought, to that of the gravest injuries, or of the mildest efflorescence, there is, when no arrest occurs, a gradual but continuous progression of the disease. This advance is commonly marked by interludes as striking as they are salutary. They may be due to the intervention of treatment, or to changes in the general health of the infected due to other causes. Apparently capricious cessation of the advance of the disease may occur, since even the cutaneous symptoms of marked cases may wholly disappear without treatment. If we were in position to view with keenest scrutiny the unmodified progress of syphilis in cell and vessel, no one can doubt that the so-called period of incubation would disappear and the microscopic eye of the observer would be as busily occupied during that as throughout any other period of the disease. Similarly, there would be no sharp distinction possible between primary and secondary syphilis. One could scarcely note the hour when, from the first to the last, there was not in progress a slow and gradual progression from point to point of the toxæmic product originating in the changes wrought at the site and at the time of infection.

These suggestions are needed for a clear comprehension of the phenomena following the stage of so-called "primary syphilis." The "primary" hypothesis made it absolutely necessary to also assume that after the primary came a secondary; and after a secondary, an inevitable tertiary stage. More, the mind thus habituated to a study of the evolution of the disease in periods, looked to an evolution of symptoms in these periods in due order and line of procession. One was thus educated to expect in a typical and uninterrupted attack of syphilis (could such be observed) each and everyone of the several manifestations of the disease. After macules, papules should appear and, in course, pustules, gummata, ulcers, and successive involvement of organ after organ of the body. Some such definiteness of order is, in point of fact, to be recognized in the evolution of variola, with which, unfortunately, syphilis has been too often and too closely compared.

But no such syphilitic history has ever been observed. It is the artificial manikin of the schools, the figment required by the domination of the medical mind by the time-rules of the French school. It was this once useful and ingenious time-schedule which made it equally imperative for the French to coin for some of the manifestations of syphilis, the striking terms, "precocious" and "tardy," words which embody a confession of the weakness of the schedule to explain all the exact clinical pictures of the disease.

Dismissing, then, the conclusions based on this wholly artificial scheme, it can be clearly recognized that, almost immediately after lymphatic adenopathy has declared to the eye and the finger of the observer that the toxic product of the chancre-site is finding its way into the vascular channels of the body, the phenomena of the disease are evolved, not in the order of a time-card but, to employ a different figure, in radii from a pathological centre. Early indeed, in many cases, can it be seen that the future of the malady is to be sought along one or another line toward exceedingly variant results. The complexus of these results may be conveniently classified in four divisions, which are named later.

Toward these the advance is either slow or rapid. The gravest may be imminent when the chancre is yet unhealed, the adenopathy unrelieved, the lymphangitis discernible. The mildest may be attained when months have passed, the early accidents well-nigh imperceptible or forgotten, and the general health of the infected individual meanwhile not manifestly impaired.

Whether this apparent interval (the so-called "secondary period of incubation") be brief or protracted, none can doubt that when an ultimate evolution of the disease occurs there is a continuous progress toward complete or partial systemic intoxication. When well marked, this apparent interval occupies from forty to fifty days, but it has been noted as brief as twenty days and as prolonged as a twelvemonth. Its limits are usually defined between the date of the chancre's appearance on the one hand, and the date of the first cutaneous exanthem on the other. That this is a purely artificial distinction becomes at once apparent when one of these dates of limitation is questioned. There is nothing in a cutaneous exanthem which entitles it to pre-eminence above other symptoms of syphilitic invasion perfectly evident during the so-called second incubative stage. From the date first assigned to the last arbitrarily selected there is no real pause, no conspicuous absence of invasion-signs. On the contrary, the symptoms of this period are often more suggestive and significant than when, for example, the skin of the patient's belly is merely sprinkled with a macular syphiloderm.

The merest enumeration of symptoms possibly occurring in this period of apparent pause, is sufficient to indicate that no real incubation can be observed. Yet here again it is important to note that not all of the enumerated symptoms are to be observed in one individual, and further, that they observe no definite order when two or more chance to be parts of one syphilitic history. Rather are they different surface indications of the several lines along one or another of which the disease may advance toward its ultimate results.

After the chancre appears, and before the first exanthem of general syphilis follows, the condition of the average patient is far from an apparently sound health. The blood-globules commonly decrease, while the leucocytes by actual enumeration increase in number. The glands of the body elsewhere than those in the region of adenopathy near the chancre-site, slowly or suddenly enlarge, become tumid, painless, much less indurated than those first noted in the disease, and are often symmetrically, rather than, as in the other instance, asymmetrically involved. The spleen, so intimately is it concerned with the fluids traversing the vascular channels, becomes tumid and at times tender. The liver function is often disturbed, as shown by an icteroid skin with muddy conjunctivæ and the appearance of bile-products in the urine. The functions of the stomach, of the bladder, of the supra-renal capsules, and of other viscera, may be even seriously impaired. Continuous or interrupted febrile temperatures may be reached, the thermometer rising at times even to 105° F., the patient being not rarely treated by a physician ignorant of the nature of the effective poison for an intermittent or relapsing fever. The nervous system may seriously suffer. Atrocious neuralgias, substernal and periosteal pains, pains in the bones and joints, osteoscopic sensations, and even synovial effusions, may be the protest of the system against the advent of the recently introduced poison. Often there are signs of mischief even of a severer type. The lassitude and

depression are profound; a condition of mental hebetude gives place to partial syncope; a headache results in a temporary strabismus, a pain in the upper or lower limbs is followed by muscular contracture. None can doubt that in a carefully studied case where the evolution of syphilis is actually in progress, however mild its future is to be, a skilled diagnostician could recognize, at one point or another of the body presumed to be in the stage of this so-called secondary incubation, unmistakable evidences of an insidious advance of the malady.

The term "explosion" has been repeatedly employed, with many other metaphorical phrases, to describe the moment when the first cutaneous exanthem appears. Its use is an index of the absurd and most extravagant importance attributed to the onset of skin symptoms in early syphilis. As a matter of fact, the latter are surface indications of more serious and deeper processes (probably involving the nervous centres) and are all-important to the eye only of the vulgar. As a matter of fact, too, they never occur by explosion. The first efflorescence of the disease may be as gradual as the dawn of a day and as impossible to define. Before the human eye traces its first expression, the camera of the photograph can produce with fidelity the faint mottlings of a skin that is to be later visibly the seat of a syphilitic efflorescence. No one who has with minute care watched the oncoming of the cutaneous manifestations of the disease, can have failed to note how insidiously the approach is made to the eye. An accident may change all. The excessive heating of the body in a bath or by dancing, may simply precipitate the blushing of the first rash.

This once apparent, and let it be noted even without this, syphilis exposes its advance in numberless directions, probably in no two cases exactly the same. These advances may be, however, for practical purposes, classified in four principal directions, as previously suggested in these pages. They may be named and briefly sketched as follows:

1. Benignant syphilis with mild and transitory symptoms.

Every vaccinicultnrist has recognized the fact that a few heifers fail to respond to all efforts to inoculate the udder with vaccinia. The reason is not explained; the system of a few individuals in every thousand simply refuses to react against the introduction of the poison. No expert of wide experience can fail to have been impressed with the fact of the existence of this exceptional class of human subjects with respect to syphilis.

There are persons who exhibit typical chancres with characteristic adenopathy of the vicinage, who never after exhibit the slightest signs of systemic disease. The objection to this statement is suggested at once to the mind of the profane. It is, that an error was made in the diagnosis of the initial sclerosis. That which seemed to be a syphilitic chancre was really not such, but spurious, an imitation of the genuine lesion. But, it is responded, such chancres have been not carelessly, but with exquisite skill, studied by experts, and found not different from others followed by grave syphilis. Further, the persons enjoying this immunity have failed later to contract the disease when exposed to it; and, more important than all else, individuals of this class correspond to others of the same class who, having actually exhibited such chancres, do later have systemic symptoms of such mild type as to astonish those unfamiliar with these singular exceptions to the rule.

These interesting exceptions are either the triumphant proofs of the skill of the physician, or (what is far more probable) proofs that some of the phenomena of natural law defy ultimate analysis by the human mind. Persons of this class have typical, severe or mild, premonitory chancres. In due time, they have also slight ganglionic engorgement, post-occipital, along the nucha, or in the line of the sterno-cleido-mastoid muscle. An exanthem occurs, of macular type, upon the belly, over the chest, slightly upon the face, or perhaps limited to the trunk. When this fades, with or even without medical treatment, the disease is absolutely at an end. The ignorant declare that ten, fifteen, or twenty years after, this individual will suffer from a gumma of brain or liver, and be the worse for the mildness of his early syphilitic history. But some of these patients have been watched during the longer of the intervals named, without signs of resulting disease. Only the obstinacy of fixed prejudice can refuse to accept the necessary conclusions. These cases are not the figments of the imagination, but are annually observed in every extensive syphilitic practice. They are not rarely seen in women who have been infected without their knowledge by a husband, or by the innocent contacts of daily life.

2. Benignant syphilis with relapsing or persistent superficial symptoms.

Cases assignable to this category are those in which typical chancres are followed by typical early manifestations of general syphilis, the patient continuing, for months or even years after, to be annoyed by intractably persistent or relapsing, but wholly superficial syphilitic symptoms. If described according to the former phraseology, these would be classed with the subjects of prolonged secondary syphilis, never proceeding to tertiary stages. Two, three, and four years after infection, such subjects are found with an infiltrated patch of scaling papules on buttock or back; with mucous patches of lips, tongue, or fauces; with a squamous palmar or plantar syphiloderm; or with a cluster of superficial and crusted papulo-pustules over the occiput or temple in the pilary region. After alternately trying and tiring of all methods of treatment, the disease at last yields. Throughout all, from first to last, there is no sign of a formidable malady. When recovery has at last occurred, no trace is left on the body, of the infective process. There has been no deep ulcer; no cicatrix; no permanent impairment of any organ or tissue. The disease, viewed in retrospect, has been perhaps a long, but always rather an annoying than a dangerous affection. It may never have for a day prevented attention to the routine work of the sufferer. Had it not been for the incidental apprehension of the future, it would not have attracted serious attention nor demanded assiduous care.

Such, without any question whatever, is the course of the majority of all cases of syphilis. They are watched with intensest anxiety by many physicians, lest the serious phases of syphilis ensue, and with feverish alternations of hope and despair by the nervous and instructed of those who endure the ordeal. It is these which furnish the text for the prophets who claim that, however mild be these histories, each is liable to result in the graver forms of the disease, and that which determines the difference is treatment, always of highest importance. Against this palpable error, an error fostered by the pitiless time-schedule of the French school, it is proper to protest. The most superficial study of syphilitic statistics demonstrates without flaw, that the majority of all patients, with the best, with the poorest, and without treatment, escape what has long been termed tertiary syphilis; in other words, do not exhibit the destructive types of the disease. The percentage of the latter to the former, in both hospital and private practice, has been estimated at the lowest at about seven per cent., at the highest at nearly thirty per cent. The corollary, therefore, is wholly trustworthy that at the least two-thirds of all patients in all countries, and subjected to all methods of treatment or none (homœopathy, ignored cases, expectant treatment, "mind-cure," etc.) escape the destructive ravages of the disease. It is upon this issue in the immense majority, and not upon the dreaded results in the minority, that the evolution of syphilis in the average of cases is to be predicated. Nothing that is here set down is to be interpreted in denial of the equally palpable fact, that the mildest case of syphilis at the outset may become the severest in the end; that the patient fairly launched in the direction of benignancy may be mischievously turned in a different and more dangerous course; that scientific treatment of the disease furnishes one of the greatest triumphs of human ingenuity and skill. It is here intended merely to look at the results of the evolution of the disease, among all classes of men and in

all countries, from the broadest point of view. The lesson taught, not for the one case but for the many in such a study, is that in this second category of mild relapsing or persistent superficial symptoms, are wholly included the immense number of all cases and of all phenomena of the disease.

3. Malignant syphilis with relapsing or persistent profound symptoms.

A recent French writer has well distinguished between the syphiloma that resolves and that which degenerates. In this third category are included all patients exhibiting gummatous lesions that are either resolved and do not return, but leave serious consequences behind; or that are resolved and return later with serious consequences after either or all outbreaks; or that persist with no less harmful results. Here, too, are variations from the less to the more dangerous grades.

Anyone of these conditions may develop after the patient has exhibited only such lesions as would justify his being classed in the category just considered. But it is highly important to note that all the symptoms here described and catalogued may succeed the chancre stage without intervention of milder symptoms, and also without an important interval of time. Early, indeed, after the chancre has healed, often before this last is completed, there are indications of the evolution of the disease toward a malignant type.

The "malignancy" of this class of cases is seen in the deterioration of the general system and the production of a syphilitic cachexia, without absolute destruction of the tissues of the body. Gummata that never ulcerate or degenerate may form in the skin, subcutaneous tissue, bones, periosteum, periarticular and articular tissues, mammary gland, testis, or other organ. By the production of pain; by displacement or mechanical effects; by a subtle influence that is difficult of analysis on chylopoësis, sanguification, or nutrition, and by interference with other functions, a disastrous influence is exerted that justifies the term malignancy in describing the course of the disease. Its effect is most striking when the structural lesions are few and not in themselves grave. A patient with merely a submaxillary lymphoma or periosteal gumma, or with an obstinate pachymeningitis producing injury by pressure-effects rather than by destructive action, may be in a graver physical state than another with a profound ulcer of the leg or of the throat.

In this category are to be found the smaller number of all cases of syphilis. It is pre-eminently the category of the transitory. They who have suffered from a syphilis trending along these lines, either by force of good management, or as a result of the self-limiting energy of the disease or the reverse of these, are readily transferred to the class just described or that which is considered below.

4. Malignant syphilis with relapsing or persistent and profound lesions that are ultimately destructive.

In this category are classed all those patients who exhibit the worst phases of what is called by the French "tertiarisme," the symptoms which have made the disease to be dreaded as much as any of the pestilences that have visited destruction upon the human family, the histories which have engendered the popular and quasi-professional belief in the non-curability of the disease, those which have led philosophers to wish that the disease were one that kills, rather than one that can so frightfully mutilate without killing.

Here the resolving or disintegrating gumma opens an avenue to ulceration that pierces through connective tissue, cartilage, periosteum, and bone; to resorptive results which, when the gumma has disappeared, leave in its site shrivelled secreting cells, nervous, hepatic, renal, osteoid; that leave the testicle a shrunken miniature of its former self; that leave a sclerotic tissue in the place of brain-cells or spinal cells, whereby one-half of the body loses its motor function, or a portion of the brain its ability to preside over the function of speech. Here, too, remote as are these formidable consequences on the time-schedule of the French school, all are obliged to admit that but a few weeks may intervene between the chancre evolution and the worst ruin. In a few days, while yet the induration of the chancre persists, the hard palate may be perforated as readily as the finger may be pushed through a sheet of wet paper; or a liver may be stuffed with ominous nodules; or the surface of the body ploughed here and there with deep and even gangrenous excavations where a gummatous infiltration has rapidly melted to destruction. It is true that for the most part these grave results occur between the third and fourth years after infection; but the facts of earliest appearance of so called late symptoms in syphilis are by none better attested than by the French themselves. It is they indeed who have coined for science the phrases "malignant precocious syphilides" and those of similar import. It is they who freely admit that the malignancy and precocity are in these cases intimately associated. It may even be asserted as a fact that the majority of all truly malignant manifestations of syphilis are precocious to the extent of violating the old rule of tertiary syphilis as a sequel of an orderly and classically developed secondary stage. It is the characteristic of these dreaded devastations of the malady, that they are early declared and rapidly evolved as extremely formidable types rather than as dangerous complications or perilous sequels of lues. Even with the chancre unhealed, the surface of the body may be in these cases riddled with sloughing cavities. It is also the French, who, confessing that these are the cases inexplicable by their formula, have coined for them the significant and comprehensive appellation, "galloping syphilis."

Between the four main lines of evolution briefly delineated above, there are to be recognized clinically innumerable variations in the direction of both mild and severe symptoms. That these types mutually merge and are to a degree interchangeable by the accidents of environment, constitutional influences, and treatment, cannot be questioned. It is, therefore, important to inquire, what are the determining causes which make the syphilitic attack of one individual so different from that of another that the physician, who is quite qualified to make a diagnosis at sight of the one, so utterly fails in the case of the other that the disease may actually progress for years under his observation without being recognized.

Our ignorance at present of the limitations of existence and of development of the germs whose toxine produces the disease, wraps many of these causes in mystery. But upon some of them one may pronounce with reasonable certainty.

For a certain school of writers the chief difference between these variations in the expression of the disease, is the absence of all treatment, or the several extremes of ignorant, indifferent, or scientific treatment of the disease.

A Study of the Causes Effective in the Production of what is Termed by the French "Tertiarisme;" or the Symptoms Grouped together in the Fourth of the Classes Described above.—One thousand cases of syphilis in private practice were selected for study in the consecutive order of their application for relief. The cases were selected from private rather than from public practice, because it is the patients of this class rather than those who fill our hospitals, who are most anxious when infected to make inquiry as to what the future has in store for them; because theirs are not selected cases, as are those in the hospital wards, where as a rule, on account of lack of accommodation, only the severer forms of the disease are admitted for treatment; and chiefly because private patients, as distinguished from public, furnish us with the fruits of a patient study of the disease after its skilful management, demonstrating its amenability to hygienic measures, the medicinal here often playing a minor part.

Of the one thousand syphilitic patients thus registered, there were 79 affected with tertiary syphilitic manifestations, a percentage of 7.9. Rollet estimates that the proportion in the south of France is five per cent. as a minimum. Diday once thought it to be six per cent., but now considers that that proportion should be doubled. Mauriac believes that the figures should be between five

and fifteen per cent., and more precisely either eight, ten, or twelve.

Of the number applying, sixty-five were males and fourteen females, a disproportion once believed to be due to the decided and remarkable preponderance of nervous symptoms in the male sex. This difference is noted also by others as in large part due to the fact that men are, more often than women, aware of the essential cause of their late symptoms, and apply for relief of the same to physicians supposed to be competent in such matters; as well as to a fact not to be ignored, that the accidents to which men are exposed in the occupations and trades often co-operate effectively with the disease itself in evoking tertiary manifestations. Of the patients whose cases are here tabulated, eleven were treated for both early and late symptoms, but this does not represent exactly the proportion of tertiarisme in the practice of a single individual, seeing that in our large cities so many patients change both their residence and their physician for diverse reasons which do not concern us here.

Of the entire number, six only were profoundly cachectic; and among the latter are found the few patients in the list changing their social conditions, as only Americans manage to do, shifting from the class of hospital and public patients to that of a somewhat higher grade. The average weight of these six cachectic patients was but one hundred and twenty-four pounds; of thirty-four, in fair health otherwise, whose weight was ascertained, the average was one hundred and sixty pounds, a weight, it will be seen, above that of the average hospital patient, and pointing to a fact well recognized by those familiar with the curious features of this disease, that not rarely its grave tertiary manifestations occur in persons of good nutrition and fair vigor. The danger, indeed, of tertiarisme lies in extremes of weight. If it be a portent of mischief to find the infected individual much below the normal weight, it is scarcely less unpromising to find the patient enormously above the weight that belongs to his or her height and age. The fat and the fleshy pay a high price per pound when immunity from tertiarisme is to be purchased.

In 75 cases where was ascertained the length of time after infection before there were evidences of "late" syphilis, the average was five years, two months, and a few days; but if we exclude from the list 9 cases where the disease had been unusually prolonged, lasting, respectively, for ten, ten, twelve, twelve, fourteen, fifteen, sixteen, twenty, and twenty-five years, the average of the remaining 66 cases is but a trifle over three years, falling thus within the average quoted above. In further corroboration of the data of precocity previously suggested, it is interesting to note that no fewer than thirteen patients exhibited their so-called late symptoms within one year after infection, the symptoms being, as usual in all such precocious phenomena, formidable. The average age of the patients in this list was some few months over thirty-four; but if we exclude from the category the ages of eight patients (three women and five men), who were fifty years of age and over, the average of seventy persons, the duration of whose life was ascertained, was but a little over thirty-two; emphasizing thus the fact that we must look for the greater number of all the manifestations of this disease between the second and fourth decades of life. Of 290 cases collated by Haslund, of Copenhagen, nearly one hundred and seventy were those of patients between the twenty-fifth and the thirty-fifth year of life.

An examination of the symptomatology in 96 cases reveals several points of interest. The organs affected were, in 47 cases, the derma, subcutaneous, and adjacent tissues; in 11, the bones and periosteum; in 11, the brain and cord; in 7, the soft and hard palate; in 6, the tongue; in 7, the testes; and in one each, the vulva, the eye, the kidney, the rectum, the muscles, the lungs, and the joints. Fournier, of Paris, reported before the International Congress of Syphilography and Dermatology in Paris, in the year 1889, the fruits of twenty-nine years of private practice in the French capital. In these twenty-nine years he had been able to study 2,600 cases of tertiary syphilis occurring in private patients. Some of his results were in the highest degree confirmatory of the important data of tertiarisme given above. But he also demonstrated that among 3,429 instances of tertiary manifestation, he had tabulated 1,085, or nearly thirty-two per cent. of cases, in which there was some involvement of the brain and cord. Haslund, of Copenhagen, has studied patients treated in the Communal Hospital of his city. Of 514 cases of tertiary syphilis observed by him there, there were 133 of involvement of the nervous and other systems, or a percentage of the latter to the entire number of cases of twenty-five; while the derma was implicated in 290 cases, a percentage to the whole of nearly sixty. Among Americans the statistics of private practice indicate that the nervous system is involved in but a trifle more than thirteen per cent. of all forms of tertiary syphilitic manifestations under observation; while the derma and its connections were implicated in about sixty per cent. of all cases.

The order of importance of the recognized causes of grave syphilis requires careful investigation. Among the accepted and recognized causes of late syphilis, that should be chief upon the list which Neumann names as second, Haslund as the seventh, and other writers on the subject as in places of varying importance. This is the constitutional condition of the patient. For him who aims to be exact and who has the fewest vagaries in diagnosis to answer for, this does not mean in private practice that the patient suffers from that catalogue of glittering generalities commonly summed up as "scrofula, tuberculosis, scorbutus, and rickets." As respects tertiarisme these latter are names and scarcely more. The more tangible conditions of the constitution, chiefly effective in furnishing the field for the display of these lesions, are malnutrition from whatever cause producing a marked decrease in the weight of the subject (note average weight of the cachectic subjects registered above); and also the excessive weight of patients who are more fleshy than the average, a class in private practice decidedly outnumbering the others.

Second only in importance, and often indeed co-operating with the cause already named, may be placed Neumann's third and likewise Haslund's third class of causes, viz., the agencies producing debilitating effects upon the system, including among men alcoholism and excessive tobacco usage. The alcoholism of private practice does not mean that of the habitual drunkard of the pauper class, nor of the day laborer who, once a week or even more often, becomes intoxicated. It means the drinking of men in clubs, of men who go on 'Change, of men who have supplies of this character in their own homes. It means the pallid-faced lad inhaling the fume of his medicated cigarette at the rate of a package daily. All other debilitating agencies (anxiety, affliction, overwork in business or profession), all that engender anæmia, loss of vigor, neurasthenia, are here properly included.

At the foot of the list should be placed that which Neumann sets at the head, and Haslund in both first and second places, viz., complete absence of treatment, insufficient or injudicious treatment, and even intolerance by the patient of mercury. These are effective causes of tertiarisme; when effective at all, we find the results formidable, and even frightful. But they are not necessarily effective. Many patients with no treatment at all, thousands of patients with the very poorest and most ignorantly directed treatment, escape tertiarisme. It is idle to deny it. Hundreds of patients, after the best directed treatment efficiently and thoroughly pursued by the most skilful of experts, have marched down to tertiarisme with steps that admitted of no pause nor arrest. In private practice, as contrasted with public practice, absence of, or defective, treatment possesses a minor significance. There are more men than women suffering from the "late" symptoms of syphilis; yet women are conspicuously those whose syphilis is most often unrecognized, and therefore longest untreated. A cause of this sort, in order to account for the occurrence of a large number of cases, should operate generally; it is impossible to assert this of the different grades of treatment employed over

the world for the relief of the disease. Looking at the immense number of cases subjected to observation in all civilized and uncivilized countries, and making allowance for the very imperfect methods adopted in different countries, and for the absence of efficient treatment in many, it is at once noticeable that as many grave cases are catalogued in London, Paris, New York, and Chicago as among the degraded classes in Italy or Spain, or among the negroes of America, all of whom are little likely to be influenced in their diseases by scientific treatment. As a matter of fact also, in the gravest of galloping cases, as every candid observer must admit, it is idle to assert that there has been time for even the amplest and best-directed treatment to save the patient from malignancy, or for the very poorest or the absence of all medication to be responsible for the grave result. An efficient and demonstrable cause should be best declared when the result is immediate and striking.

Again, it has been surmised by authors of repute that the difference in these cases is explicable by a difference in the activity of the germ, or by a variation in the intensity of the virus. But to this a negative is clearly set up by the citation of innumerable cases where, of several individuals infected from one person, no two exhibit the same degree of virulence in the character of the symptoms induced. The same is shown by confrontations in a series where the individual infected from the gravest types of the disease has mild syphilis, and another contracting the disease from this mildly affected patient pays a heavy forfeit for the occurrence of the accident.

Critically examined, the problem speedily resolves itself into a question concerning chiefly the soil in which the germ is planted, and the favorable or unfavorable conditions under which it develops and fructifies, the first of the efficient factors above enumerated. These are causes which operate equally in all countries and under all skies. Looking at this field critically, we are at once struck with the fact that syphilis here aligns itself with all other diseases that in extreme conditions may destroy the race. Here, as in equally chronic tuberculous processes, in protracted cases of inflammation of lung, kidney, or liver, the debilitated, the exsanguine, and the congenitally weak, suffer more seriously than the men and women of brawn, of blood, and of vigor. Here operate with impressive energy the causes catalogued in the etiological chapter of every work on special diseases—alcoholism, debauchery, pauperism, hospitalism, "misery," in the large sense in which the French use that term, and the wasting effects of all precedent illnesses and injuries. With other diseases, let it be noted in passing, there is small tendency in syphilis to combine. All have noted the smallness of the number of cases in which syphilis has coexisted in one individual with tuberculosis, carcinoma, or sarcoma. One might almost assert that it is with lepra alone that the disease has been in the history of medicine mingled to confusion.

Apart from the causes suggested above, it is well known that very fleshy persons, the aged, and very young, are exceedingly liable to suffer from severe forms of the disease. Young adults of both sexes, neither fleshy nor thin, with good development, fair inherited vigor, and not debilitated by any acquired vices or exposures, commonly escape the serious issues of lues. It is an interesting commentary on the preponderance of causes effective in the production of grave syphilis, that decidedly the simplest cases, as regards the evolution of the malady, are those of persons accidentally infected where knowledge of the nature of the accident is speedily acquired.

It is then, by the operation of the several causes suggested above, rather than by the activity of the acquired virus, that the infected cases range themselves in the categories of evolution briefly described above. In the fourth, which includes the destructive and formidable ravages of the disease, there will always he inscribed the largest number of names of the cachectic, the dissipated, the aged, the impoverished, the filthy, the neglected, and the weak.

This all admitted, it is scarcely necessary to further affirm that there are few triumphs of mind over matter to be compared with the brilliant results obtained in a systematic and skilful treatment of this disease—results sufficient in many cases to determine whether any given subject shall be exchanged from one to another of the several classes here described; or be in fact so slightly infected as scarcely to deserve recognition in any one of the four.

The Relations of the Syphilodermata alike to the Process of Systemic Intoxication and to the Accidents of Environment.—The view was once generally held, and is still largely entertained, that the several eruptions observed in the course of evolution of syphilis are due solely to the constitutional malady. This position, viewed in the light of modern science, is seen to be wholly untenable. The eruptions so minutely described and definitely catalogued in the treatises upon this subject, can, without difficulty, be assigned etiologically to several categories.

In the first are grouped syphilodermata due solely, so far as can be ascertained by our present methods, to the influence of the toxine of the disease. These eruptions constitute probably the smaller number of all with which the physician needs to be familiar. If an infected person of either sex, of average health and weight, could be kept under proper treatment during every moment of the duration of the disease, the body in a perfectly aseptic condition, its functions performed according to a physiological standard without the operation of any unfavorable external influence, it is probable that from first to last the sole eruption visible would be a generalized macular exanthem, after whose fading the skin would present no further morbid efflorescence. What other among the exanthemata of syphilis may be as strictly related to the natural evolution of the disease, it is difficult to decide. Certain it is that this is the sole eruptive feature of many cases; and one may suspect that when others follow, if we were wiser, the accidental cause could be appreciated. Even in this as with some others, we do not find the cutaneous symptoms pointing to an effort on the part of the system to eliminate a peccant humor, but as can be recognized in the circinate grouping of many of the earlier syphilodermata, rather to an irritative condition of the nervous centres as a result of which the eruptive phenomena are awakened.

In a second category are to be recognized a number of syphilodermata due wholly to externally operating causes, the accidents of environment. Many of the pustular eruptions should be here included, where manifestly the pyogenic staphylococci are the efficient factors in the production of the lesions, some of them resulting from inoculation, others from auto-inoculation. It is quite noticeable of the pustular syphilodermata, that they are nowhere seen so abundantly and in such typical expression as among the filthy, the impoverished, and the neglected. They are decidedly among the rarer complications of the evolution of the disease among the cleanly, the well fed, and the comfortably clad. It is further interesting to note that specific treatment so-called, being for the time abandoned, the pustular syphilodermata as a rule respond rapidly to the treatment indicated by the existence of such lesions, viz., bathing, disinfection, antisepsis, proper clothing, and shelter of the body. Some of the pustulo-crustaceous and bullous lesions acknowledge similar causes. It is an error to disassociate syphilis in all cases from the category of the filth diseases. The worst varieties of the malady, without any question, are to be found in the lowest class of patients in the out-departments of Public Charities, both in Vienna, Paris, London, New York, and Chicago, where attacks are daily made upon the unwashed skin by micro-organisms, animal and vegetable parasites, the "Flora Dermatologica" of Unna, and the finger-nails of the wretched sufferers.

In a third class are to be recognized the eruptive phenomena due without question to the operation of an internal cause, but brought into existence, or encouraged, or precipitated, by externally operating accidents. This includes an enormous number of all the syphilodermata, and there are few that may not acknowledge influences of the sort to which attention is here directed.

The mouth of the tobacco-chewer and smoker is often

freed from mucous patches when relieved of the irritation thus aroused; the anus of the infant is no longer surrounded by a group of condylomata when its surface is properly cleansed and disinfected; the palmar plaques of the toiler with material or tool cease to ulcerate and begin to heal when labor is suspended, or the hands, when thus engaged, are protected from injurious contacts.

In a fourth class are to be placed a small number of supposed syphilodermata due to causes operating internally, and to be attributed only in part to the infective process. Here should be described all the medicamentous eruptions due to the iodine compounds properly and improperly administered for relief of the disease, chiefly the acneiform lesions (acne artificialis, acne varioliformis). With these should be enumerated eruptions of the class represented by the pigmentary syphiloderm which refuses to succumb to the action of the remedies commonly effective in syphilis, and which is in reality a pigmentary disorder only very indirectly associated with the toxic condition of the system.

In a fifth class are represented a number of the cutaneous pictures of syphilis due to the commingling of syphilodermata with simpler dermatoses. Chief among these is the combination of syphilis and seborrhœa seen so often about the nose, the brow, and over the scalp of the subjects of the two disorders.

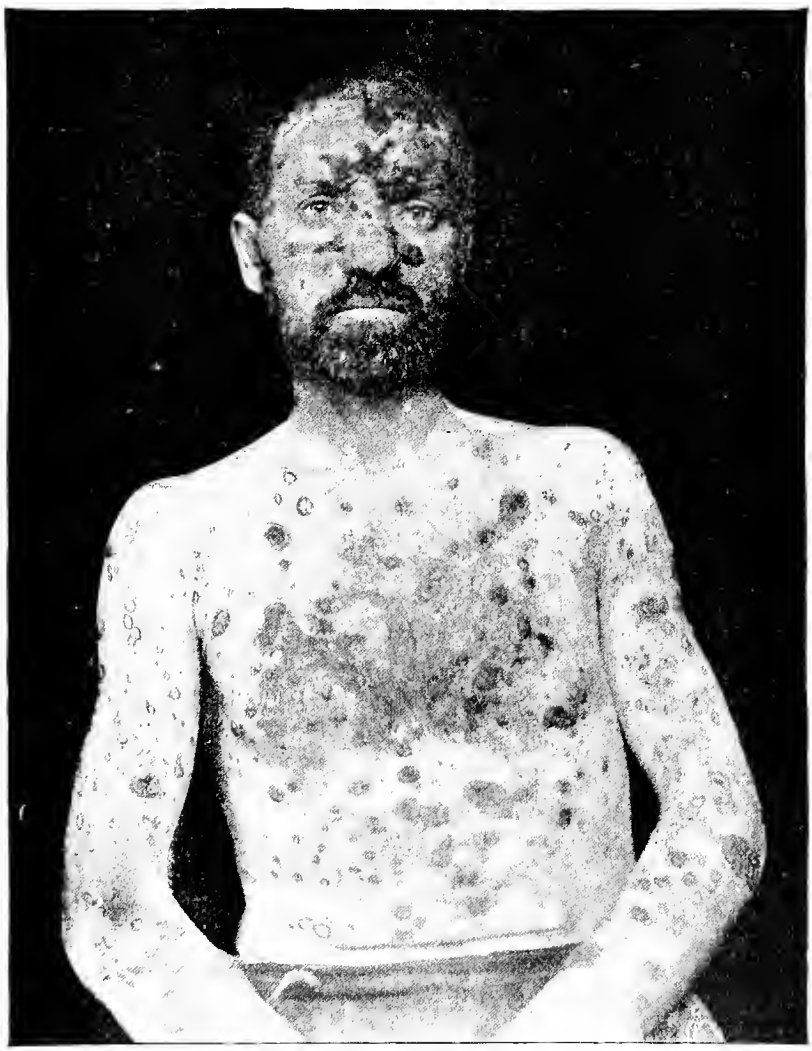


FIG. 597.—Pustulo-crustaceous Syphiloderm as exhibited upon the skin of a neglected and filthy subject of the disease. (Rupia.)

THE BEHAVIOR OF THE SYPHILODERMATA IN THE PRESENCE OF OTHER INFECTIVE PROCESSES.—The knowledge had respecting the relation of syphilis to other diseases, was of the vaguest character prior to the date of an exact appreciation of the etiological importance of micro-organisms in disease. The mutual antagonisms of the latter in several of the infective processes are made apparent in many of the morbid conditions presented in syphilis. Erysipelas may affect the skin which is the seat of syphilodermata, but then the result, far from suggesting a complexus of two disorders with a confused picture of each, is a typical erysipelas having an issue which leaves the skin, after relief of the later infection, free from the lesions first occupying the ground. Similarly, in observation of a series of cases of typhoid fever occurring at the moment of an abundant eruption of syphilodermata of an early type, the cutaneous symptoms wholly disappear with all other traces of syphilis, only to return, usually in milder expression, after the conclusion of weeks or months of illness and protracted convalescence, when the bodily weight is again nearly approaching its normal standard.

VALUE OF THE CICATRICES OF SYPHILIS FROM THE DIAGNOSTIC POINT OF VIEW.—Every physician should be thoroughly familiar with the scars left by syphilis. When perfectly typical, they resemble nothing else in the entire scope of pathology than a relic of the syphilitic process.

First. They are often elegant rather than clumsily wrought. The ulcers of late syphilis are often so formidable and threatening that he who is not expert will not foresee how delicately and beautifully repair will be accomplished and the evidences of mischief smoothed away after the lapse of five, eight, or ten years.

Second. As syphilitic ulcers are commonly rounded in outline, so these peculiar scars are in circles or parts of circles, giving the semi-lunar, quarter-moon, and gibbous outlines, with combinations representing the figure of three, or of eight, the letter "S," the form of the kidney, of the horse-shoe, and of the dumb-bell.

Third. The pigmentation they exhibit is peculiar. It is best studied naturally in the lower extremities, where, as in the cicatrices following traumatism and healed varicose ulcers, the staining from coloring matters brought thither by the blood effused in excess in and about the part, is most conspicuous and persistent.

There is no question but that individual and race peculiarities influence the degree of this staining. It is marked in many deep brunettes; it is rarely as disfiguring in very light blondes. In the scars of syphilis, the color in the cicatrices following freshly healed ulcers, is at first that simply of hyperæmia, dull-reddish, purplish-red, occa-

sionally even pinkish-red. As the infiltration subsides, the color becomes more apparent, till there is every variation from the deepest chocolate to the lightest brown, evenly tinting the scar-tissue and staining, in some cases more than others, the integument beyond the outer wall of the cicatrix, forming a species of pigmented halo, half or a full finger-nail in width, and corresponding in shape to that of the ulcer which preceded, semi-lunar, kidney-shaped, etc.

After a period lasting from a few months to as many years, the process of decolorization begins in these singular-looking stigmata, the difference of time stated depending largely upon the general vigor of the patient, and upon his or her occupation, a prolonged observance of the erect posture, as in wheelmen of vessels and tramdrivers, being unfavorable to rapid removal of these coloring matters.

The entire process of decolorization may be concluded in three or four months, but may require a much longer period. It is rather more rapid in women than in men. A completely decolorized scar of the leg, wholly destitute of undue pigmentation in a male patient of average weight and vigor, commonly points to a syphilitic infection from six to twelve years before, unless the decolorization has been completed and the scar has remained practically unchanged for some time. Then, of course, one can often verify the fact that fifteen, twenty, or twenty-five years have elapsed since the date of infection.

This wholly decolorized scar is perfectly distinct texturally, though suggesting to the scientific eye that can read its past history, that it is faded. It is smooth, unattached, occasionally picked out in points, as though one had treated it with the tool of the engraver or the burin of the etcher. Its color is that of the familiar dead-white of an old scar; but very rarely indeed is it rigid, puckered, or elevated as in spurious or true keloid. Occasionally, even when quite ancient, there is an appearance at one or more points of a thin scale which may be detached from its surface. Its conspicuous features are its delicacy and its thinness. It may be with great readiness plucked up from the tissue beneath, between the thumb and finger. It is best compared with a thin sheet of mica lightly let into the skin. It is very slightly depressed beneath the general level of the integument.

Repair has been so finely wrought in such a case that as one sweeps the fingers over the surface, it can scarcely be recognized by the touch where the new-formed tissue exists; and the movements of the limb may not cause the slightest puckering of the skin where the scar is formed. It answers admirably all the needs of the part, save that it does not furnish in normal measure sweat or other secretion, and but few, if any, hairs appear upon its surface. Few would suspect upon examination of this superficial and at first sight insignificant patch, that it had been once the seat of a deep, exquisitely painful, and even formidable ulcer, boring within to the very lowest stratum of the panniculus adiposus, and causing in some patients more apprehension than a fractured leg or an apicial pneumonia.

There are some variations of this typical portrait which must be studied. Almost every syphilitic cicatrix of the size of the section of an egg or larger, if examined with care, will be found to be made up of a congeries of smaller lesions, each of which is possessed of the characteristics of the larger. The mode of grouping of these smaller scars, each perhaps as large as a thumb-nail, is quite in accordance with the law of the circle suggested above.

Sometimes, rather more rarely than in the other forms to be noticed, a large central lesion is surrounded by a circlet of the smaller, suggesting the familiar arrangement seen in a brooch set with pearls. Again, we have the so-called "satellite" figures, a larger patch with one or two of the smaller set on the edge; or the figure is strikingly like that of a trefoil or quatrefoil slightly distorted from the strict architectural pattern. At times the patch is made up wholly of these small finger-nail sized circlets, compactly gathered within an oval, roundish, or circinate outline, the componnd lesions conforming in every detail to the description attempted above.

Studying these combinations, whether in the figures selected for illustration or in the S-shaped, kidney-shaped, or often variously shaped figures, each component element of the group may be recognized as to age by its separate decolorization process. In a patch of this kind, one may at times see that the process of whitening is going on at nearly the same rate in each scar, all being, for example, at the moment of observation, provided with a tolerably clear or clearing centre, and a reddish or purplish rim outside the latter.

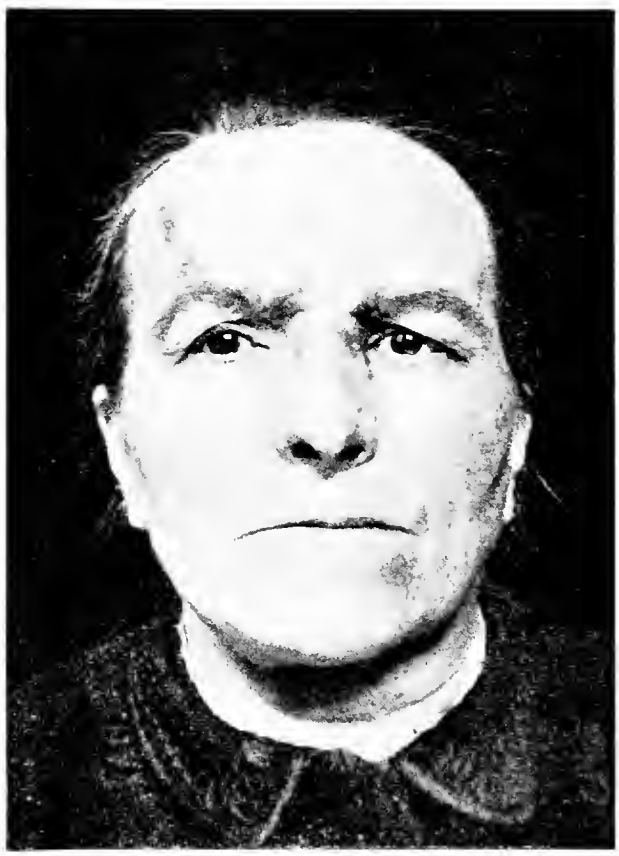

FIG. 598.—Large Compound Cicatrix of the Brow, immediately after healing of syphilitic gummata.

The still highly tinted and not wholly decolorized cicatrices of syphilis are often seen in combination with or in close juxtaposition to the ulcerative or resolutive lesions whose process originally produced them all. Thus in a circinate group a cluster of finger-nail sized scars may form the crescentic border of a patch whose corresponding incurved border is made up of healing ulcers where gummata have softened, each a miniature as to outline of the scar that will succeed.

In other regions than the lower extremities, there are always the same general characteristics with differences due largely to peculiarities of situation. On the upper extremities, for example, scars of the same type occur, with, however, very much less pigmentation, and this latter, when at all conspicuous, is removed in a far shorter time than elsewhere. Thus a group of shallow and depressed, circular, bean-sized scars, a dozen or more in number, may be seen over one or both of the olecranon

processes (a common site) quite destitute of color in six months after their first development; and the same may be said of a large saucer-sized and -shaped patch which may be seen over the point of a shoulder, near the clavicle, in the front of the upper chest, or, not rarely also, over one hip, all favorite sites of this peculiar disfigurement.

It is over the face where the type characteristics are first lost, and where confusion is most apt to arise. The causes are, first, the frequent absence for more than a few months at the most, of pigmentation; second, the configuration of the folds of the skin of the face making irregularities in the surface; and third, the interference with the natural progress of repair often mischievously directed in order to overcome at an early hour the too evident impairment of personal comeliness. The chief variations from type are as follows:

1. The multiple and almost symmetrical small-sized (pea and larger) scars left by resolving or ulcerating tubercles. These are apt to be confounded with the scars of variola, on account of their great number and the absence of the typical features of the scars we have been studying on the lower limbs. They are often no larger than pease or beans, are somewhat symmetrically, at times very irregularly, strewn over the face, and are set into the skin about as deeply as the cicatrices of the same region left by small-pox. But the differences between the two, however close may seem the resemblance, are apparent on careful observation.

The syphilitic scars of this order are seen more often and more abundantly over the upper half of the face; while the variolous relics are more generally and impartially diffused. In syphilis the scars affect the brow preëminently; and after this the temples, the outer nares, and the outer angles of the lips; often the point of the nose and the centre of the upper lip and the entire chin are spared. The marks of small-pox are often conspicuous over these last-named regions, and in well-marked cases are thickly and uniformly spread over the whole countenance, an exceedingly rare occurrence in syphilis.

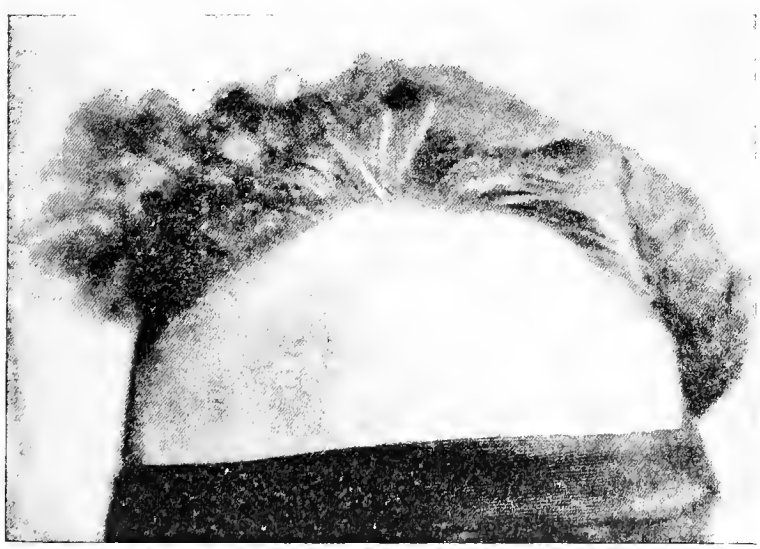

Fig. 599.—Multiple Cicatrices of Syphilitic Tubercles, one year after healing.

2. The single small, or relatively few larger deforming scars of the face, more nearly approaching those of the type studied on the lower extremities. These are illustrated by the crescentic cicatrices occasionally visible a short distance from the angles of the mouth, set into the skin of the cheek, the convexity turned toward the angle of the jaw, the concavity or plane outline next the mouth. These may be half an inch or more in diameter, and when closely studied exhibit the traces of the gummatous ulcer in outline and superficial erosive action. Such scars, too, are not very rarely displayed over the lower brow as if one had taken for a centre the point of exit of the supraorbital nerve from its foramen on one side and swept a semicircle over the brow with a radius of half an inch or more. A smaller scar of this type is formed in some patients in front of the ear, looking something like the outline of a sea-shell, semi-crescentic in contour and not larger than a thumb-nail.

3. And lastly, the wholly irregular scars of the face whose difference in type from all those previously described is due either to traumatism or the influences of special traction in the performance of the functions of the facial organs. Here may be named the strictly linear scars vertically directed along the brow where scratching has occurred or the finger-nail has torn off a crust and with it a portion of the integument directing the ulceration in a peculiar line; this is of the rarer type. Much more common, and much more important for the purposes of diagnosis, are the so-called lines of puckering at the outer angles of the lips. These, when typical in the adult, are not one whit less significant than when seen in the infant affected with inherited disease; and are usually due to the same cause, viz., the occurrence of ulceration as a complication of mucous patches in the muco-cutaneous folds about the angles of the lips. They are always radii from the long axis of the oral cavity, rarely proceed to any distance from the verge of the mouth and present an odd-looking, puckered appearance which persists through life. They are absolutely diagnostic of syphilis, being never seen with characteristic features, and especially when affecting both angles of the mouth, in any other disease.

In this same group may be named the exceedingly irregular small-sized isolated scars of syphilis found upon the face. Such are the jagged single depressions, one or two of which exist in some patients on the sides of the root of the nose, in one cheek or both, or in the region of the beard of the male subject.

The alopecias of late syphilis are all due to cicatricial lesions, or those going on to the production of cicatrices. Here is a distinct recurrence to the type presented in the leg. On examination the scar does not at first sight stand out so conspicuously as upon a non-hairy surface. One has to separate the adjacent hairs in order to gain a view of it. There is the crescentic border, the reddish or purplish hue of the surface not long healed; the deeper purple for a brief time after the healing; then the relatively rapid decolorization; lastly, the dead-white or dull-white scar, with perhaps one or two hairs only growing in the centre of the bald patch, as large as a silver dollar, or the section of a hen's egg. This is the seat and explanation of the remediless alopecia of authors, due to late gummatous involvement of the scalp.

The immense majority of chancres on the progenital region of the male subject leave no scars. The initial sclerosis is usually resolved, leaving no trace behind it of the primitive accident. The majority of cicatrices left in this region as sequels of venereal accidents are those of chancroids, the so-called "soft" or contagious, auto-infective, pustular, and ulcerative lesion of this region.

It is well known, however, that continued irritation of the initial sclerosis of syphilis may cause it to ulcerate so deeply that it will erode the connective tissue of the derma to an extent sufficient to leave a scar. Savin-cerate, caustics frequently applied, and spontaneous gangrene (rare indeed of occurrence) may induce this

erosion. There is, however, one initial sclerosis that is the seat of well-nigh constant irritation till its usually long-deferred healing is completed, and that is the infecting chancre seated immediately within the meatus urinarius. On every emission of the urine its surface is traversed by a fluid highly charged with urinary salts, and the pain in micturition is correspondingly great. The diagnosis of this lesion when in activity is made with the greatest ease without the aid of the endoscope. When the tip of the glans is manipulated by the finger and thumb of the surgeon, the sclerosed mass of the chancre is distinctly felt as though a cylindriform mass no larger than the stem of a common clay pipe and scarcely as long as a digital phalanx had been substituted for the normal urethral channel. The incessant irritation at last produces scarcely so much ulceration as it does a deeply seated erosive action which results in reaming out the meatus urinarius. When all is healed, the apex of the truncated cone, represented by the point of the glans, is seen to be lost. The acorn-shaped body is destitute of its delicately finished tip. It has an obtuse or blunt apex; and the perfect accuracy of adaptation of the lips of the meatus is forever lost. Instead, there is an odd-looking funuel-shaped gap of the mouth of the conduit, with the flaring end of the funnel directed toward the eye of the observer. This, too, is produced only by the syphilitic chancre. The gangrenous or deeply ulcerating chancroid will mutilate the glans in the most lawless manner, remove one-half or more, or even the whole of that organ, in the most irregular way, will gouge out one side or the other and leave the urethral orifice as a chasm where once the frenum stretched its slender arm for the suspension of the scrotum. But almost never will the process cease with the delicate reaming described above. Cicatrices in the groin of one side or both have no significance for the most of cases, as regards the diagnosis of syphilis.

Syphiloma of the Subcutaneous Glands.—(Gummatous involvement of the lymphatics; so-called "tertiary bubo.")

In those periods of syphilis, whether early or late, when gummatous material is deposited in any of the bodily tissues, the subcutaneous glands may suffer. This complication of the disease is far more common than is generally supposed, and when the glands of the neck are involved, presents a condition which is often mistaken for tuberculosis.

The subjects of the disease are not always in what has been termed the "late" stages of the disease. They are often the recently infected, even within a few months of the date of that accident; and as a rule are of the type formerly described as strumous. They are usually individuals of weak constitution, under weight, and poorly nourished, or severely taxed in daily toil. The glands are recognized as round or oval, dense and at times elastic swellings, involving one or a group of several glands ("pleiades," of French writers) which may pursue a gradual course terminating in disintegration, or undergo resorption of the deposit in any stage of development. The glands are at first in a purely irritative condition, thus probably resenting the entrance of either bacilli or toxine of the same in their meshes; later, there is well-marked cell proliferation with degeneration of the central pulp of the gland, pus formation, and exit of the same, either spontaneously or by means of surgical interference: in other subjects caseation results, the cell proliferation decreases *pari passu* with increase of the intercellular tissue, and fatty metamorphosis eventually takes place.

The glands most frequently involved are, first, those of the neck (submaxillary, infraclavicular); next, those of the inguinal regions; lastly, the axillary, cubital, and popliteal.

The tumors vary in size from small nuts to large eggs, are both painful and tender; and soften when about to break down at or about the central point of the mass. They are exceedingly indolent, and even when converted into an abscess have little or no tendency to burst, but retain for weeks at a time, even longer, their pulpy and ill-conditioned contents. They are at first covered by a movable and normally colored integument; later, this becomes dark-hued and livid. When spontaneously bursting the rent of the gland-capsule reveals a discolored grayish-yellow or darker admixture of thin pus and detritus of tissue, a healthy looking wound being produced after scraping, which in well-managed cases proceeds without delay to repair. The scars left in either event strongly resemble those resulting from the similar process in tuberculous involvement of the lymphatic glands.

Actinomycosis should always be differentiated by the aid of the microscope; tuberculosis, if not by the same means, at least by the relative rapidity of evolution of the process, for though at times a few months are required for the entire career of the syphilitic lesion, the tuberculous are even slower of career and soften centrally only after long delay. The lymphoma of syphilis rarely requires a twelvemonth for its completed curriculum. Carcinoma of the regions named is exceedingly rare; sarcoma even more rare of occurrence.

Gummata of the Lung.—Smaller and larger gummata, when of occurrence in the lung, are encircled by peripherally distributed connective tissue with clearly defined limits. The result, as regards the lung-tissue, is, according to Councilman, a pneumonia with fibrinous exudation, accompanied by fibrous thickening of the alveolar walls, the whole undergoing caseation. Where the action of the virus is intense, necrosis of tissue occurs before there is time for the development of the protecting connective tissue.

The analogy between tuberculosis and syphilis of the lung is shown by the fact that in both processes a caseous pneumonia results; but in the former instance the inflammatory process is the direct result of the presence and irritative effects of tubercle bacilli; in the latter, the primary process is an atrophy of the alveolar walls, most probably due to a hyaline degeneration of the capillaries.

The diagnostic differences, as given by Delafield, are, in syphilitic disease of the lung, dyspnœa on inspiration; a varying degree of supra- and infra-clavicular retraction; on percussion, marked dulness over the affected parts; on auscultation, prolonged and high-pitched respiratory murmur, with a pause between it and a prolonged and almost equally high-pitched expiratory murmur. Sibilant, sonorous, crepitant, and subcrepitant râles are often wanting; vocal fremitus on coughing is increased.

The more lately devised methods of treatment in syphilis have not yet supplanted the older and approved devices, nor do they contain the promise of so doing. Tommasoli has employed intramuscular injections of a fluid obtained by keeping the blood of lambs for twenty-four hours on ice, separating thus the serum. From two to eight cubic centimetres of the latter are injected for a dozen or more times. The lesions of syphilis are reported to have rapidly and permanently disappeared under this treatment; and the reactive effects from these injections were in no case severe.

Wellander, of Stockholm, has employed for injections a mixture of the acetate of thymol-mercury, one and one-half grain in liquid paraffin, injected every fourth day till six or seven injections have been made. Indurations and abscesses at the site of the operation were minimized in number and severity; the reactionary effects were reported mild, and the symptoms of the disease yielded with varying but satisfactory promptness, some relapses occurring.

The other mercurial salts lately employed beside hydrargyrum thymolicum (thymoloaceticum) are salicylicum succinimidicum, alaninicum benzoatum, oxycyanatum, formamidatum. The basis employed by Schadek is an emulsion of gum arabic. The oxycyanide is used in injections of one quarter of one per cent. The benzoate is employed in solution as follows:

Hydrarg. benzoat.....	0.30
Sod. chlorid.....	0.10
Aq. destillat.....	40.

The succinimidicum is used also in one per cent. solutions.

Moncorvo and Ferreira report the treatment of a large

number of young children affected with syphilis by hypodermatic injection, preferring the corrosive sublimate for this purpose. The doses were exceedingly well tolerated by the children, who exhibited but little tendency to the after occurrence of stomatitis, salivation, or intestinal colic. *James Nevins Hyde.*

TASTE, DEVELOPMENT OF THE ORGANS OF.

The development of the organs of taste in the mammalia has been studied in the rabbit and in man. According to Hermann, the development of the gustatory papillæ in the rabbit takes place during the latter period of embryonic life, and in the first few days following birth. In a rabbit embryo 54 mm. long this observer was able to distinguish, with the unaided eye, the circumvallate and foliate papillæ, but the trenches of the former and the furrows of the latter were wanting (Fig. 600). The papillæ are developed from simple proliferations of the epithelium, which penetrate the mucosa at various points. From these proliferations arise secondary shoots or processes which ultimately form the lateral lamellæ of the papilla foliata. The primary epithelial ingrowths may be seen in rabbit embryos of 54 mm. in length (*i.e.*, of twenty-three days and upward). The secondary processes, on the other hand, which arise from these, do not appear till a day later, and at birth the lateral lamellæ which are formed from them are still incomplete. The complete differentiation of the circumvallate papillæ and the folds of the papillæ foliatæ, is for the most part accomplished by the end of the first week of life. The serous glands, so intimately connected with the organs of taste, are formed about the same time as the gustatory papillæ. The primary epithelial ingrowths penetrate still more deeply the mucosa and submucosa, and, probably through atrophy of the axial cells, are converted into ducts from which radiate smaller ones to form the acini.

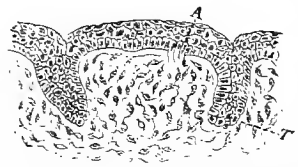

FIG. 600.—Vertical Section through the Circumvallate Papilla of a Rabbit Embryo 54 mm. long. (After Hermann.) *A*, early stage in the development of a taste-bulb. The trench (*T*) is undifferentiated.

In rabbit embryos 54 mm. in length, taste-bulbs in the first stages of formation are perceptible in the basal layer of epithelium of the free surface of the circumvallate papillæ (Fig. 600. *A*). In embryo rabbits 70 mm. long the bulbs of this area are fully developed and numerous (Fig. 601, *T.B*). In the secondary lamellæ of the foliate organs and lateral wall of the circumvallate papillæ of embryos 95 mm. long the forerunners of the definite bulbs are perceptible in the groups of modified basal cells of the epithelium. In embryos of a still later period these fusiform cells traverse the entire thickness of the epithelial investment of the papilla. At birth a few of the bulbs have matured, and by the sixth day of life their development is completed. The development of the bulbs of both gustatory areas is not fully completed till the beginning of the third week after birth, when they are no longer distinguishable from those of the full-grown animal. With the appearance of the bulbs of the lateral area those of the free surface (having attained their completion during intra-uterine life) undergo degeneration, and by the third day there is scarcely a vestige of them remaining.

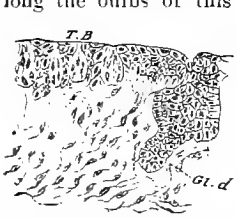

FIG. 601.—Vertical Section through a Portion of the Circumvallate Papilla of a Rabbit Embryo 70 mm. long. (After Hermann.) *T.B*, taste-bulbs of the free surface: *Gl.d*, developing gland-duct.

In man the gustatory papillæ begin to develop early in the third month of intra-uterine life, while the filiform papillæ do not appear till a week or two later. The first indications of taste-bulbs are seen at the end of the third and beginning of the fourth month of fœtal life. The bulbs develop simultaneously or nearly so at the upper part of the circumvallate and fungiform papillæ, but they have not been observed in the lateral organs of taste till a somewhat later period. The hinder portion of the dorsal surface of the tongue of a human embryo early in the fourth month is more or less marked by papillary elevations of the mucous membrane. The elevations vary greatly in size and shape, and the spaces between them are filled for the most part with epithelium. The epithelium covering the elevations averages in thickness about 0.020 mm., and does not differ very greatly in character from that investing the lingual papillæ of later embryos. It is composed of three rather indistinct layers. The superficial layer consists of somewhat flattened cells, which at its deepest part become blended with those of the middle layer. The middle layer is much thicker than the preceding, and is composed of cells spheroidal or polyhedral in form with prominent nuclei. Below this is a deep layer consisting usually of a single row of elongated, but not invariably true, columnar cells. The mucosa beneath the basal epithelium of the papilla is quite homogeneous in appearance, and very rich in nuclei and delicate fibrils. In the stroma of the submucosa, which is somewhat looser in texture than that of the mucosa, are scattered here and there minute bundles of striped muscle-fibres; but their transverse striæ are exceedingly faint and require a high power to define them. The stroma, both of the mucosa and submucosa, is penetrated quite deeply at different points by the proliferations of the inpushing epithelium. These proliferations of the epithelium indicate the future position of the mucous and serous glands and their ducts, the incipient stages in the development of which are at this period already perceptible. The process of development of the papillæ is similar in the main to that already described in the rabbit. Chains of epithelial cells penetrate the mucosa at intervals, and form the walls of the papillæ. The cells composing the middle layer of the chains gradually undergo atrophy, and thus give rise to the trenches of the circumvallate papillæ and the furrows of the foliate organs. Here and there also in the basal epithelium and underlying connective tissue of the papillæ the taste-bulbs are beginning to form. By the middle of the fourth month a few papillæ of the circumvallate type in the early stages of development are present at the basal portion of the dorsum. The more advanced of these measure 0.11 mm. transversely, and are 0.096 mm. in height. Their upper surface is flattened or slightly convex, and they project but slightly from the adjacent lingual area. The trenches are not yet differentiated, although their future position is in most instances clearly indicated (Fig. 602). Fungiform papillæ in various stages of growth are scattered irregularly over the dorsum, and the lateral gustatory organs (the papillæ

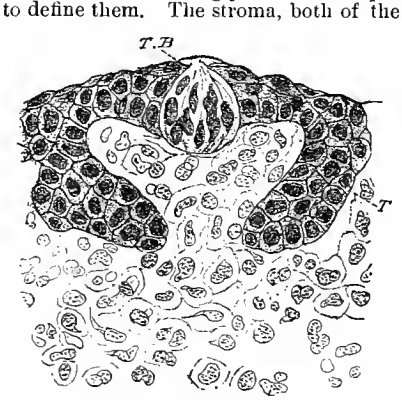

FIG. 602.—Vertical Section through the Circumvallate Papilla of a Human Embryo of the Fourth Month. (× 300.) The papilla bears a single taste-bulb (*T.B.*) the base of which rests in a depression of the mucosa. The trench (*T.*) is undifferentiated.

foliatæ) are clearly recognizable in the irregular elevations of the mucous membrane at the sides of the base of the tongue. Both the circumvallate and fungiform papillæ bear isolated embryonic taste-bulbs in early stages of development. The more advanced of these measure 0.016 mm. in length and 0.012 mm. in breadth, and lie vertically in the axis of the papilla, with their basal portion resting in a cavity of the mucosa. In general appearance the bulbs of this period are not unlike those of the soft palate and epiglottis, which probably develop later. The bulb shown in Fig. 602 is of this period. The superficial layer of epithelium having become detached, allows the bulb to project slightly above the surface of the papilla.

At the end of the fourth month the papillæ have increased in number, but there are no trenches and but a slight increase in the number of embryonic bulbs. By the middle of the fifth month the circumvallate papillæ have increased to six, and others can be seen in process of development. The trenches are not yet differentiated, the structural continuity between the epithelium of the free area of the papillæ and that investing the general lingual surface being still unbroken. The foliate organs consist of a few folds of the mucous membrane, the place of the future sulci being indicated by the epithelial ingrowths, which at irregular intervals penetrate the mucosa. The serous glands have advanced somewhat, and here and there are beginning to take definite shape. The majority of the circumvallate papillæ, and also many of the fungiform papillæ, bear embryonic bulbs on their exposed area (Fig. 603 *T. B.*). Of these, the more advanced are mainly epithelial in position, while the less mature are largely embedded in the stroma of the mucosa. Medullated nerves are fairly shown in these papillæ. Directly beneath the basal cells of the epithelium is a fine, delicate, reticulated network, from which non-medullated nerve-fibrils pass upward, penetrating the bulbs and neighboring epithelium.

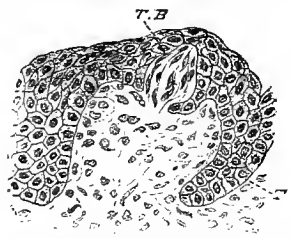

Fig. 603.—Vertical Section through the Circumvallate Papilla of a Fœtus Four and a Half Months Old. (× 310.) *T. B*, taste-bulb; *T*, trench, undifferentiated.

By the end of the sixth month all of the circumvallate papillæ are present, some of them, however, being much more advanced than others. The papillary wall and the outer wall of the trench have for the most part separated, leaving a very narrow fissure. Bulbs are beginning to develop on the lateral area of the papillæ, and are still abundant on their upper surface. In the foliate organs the furrows at their upper part are quite free from epithelium, and bulbs, partly sub-epithelial in character, are present at the upper portion and sides of the folds. At the seventh month, in some instances, the trenches and furrows contain epithelial débris, vestiges of which remain till after birth. The bulbs have increased greatly in number on the lateral area of the papillæ, and have not decreased apparently on their upper surface (Figs. 604 and 605). Many of them lie partly in the mucosa, and the ultimate nerve-fibrils, which constitute their sensory elements, can be seen within the epithelial shell where the cells of the latter have been but partially reflected over them, or where the imbrication is still incomplete. Small, spheroidal, rudimentary bulbs, deeply embedded, may also be found at this period on the anterior and posterior surface of the epiglottis, and in the epithelium of the soft palate and uvula.

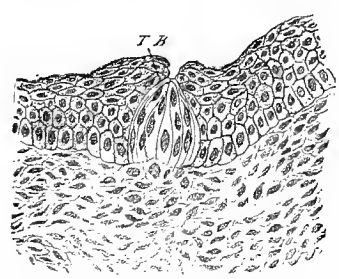

Fig. 604.—Vertical Section through a Portion of the Circumvallate Papilla of a Fœtus of the Seventh Month, showing One of the Bulbs of the Free Surface. The base of the bulb is concealed in the mucosa. (× 280.)

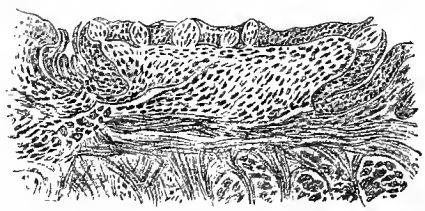

Fig. 605.—Vertical Section through the Circumvallate Papilla of a Fœtus of the Seventh Month, showing the Bulbs of the Free Surface. (× 85.)

By the end of the first month of life all of the circumvallate papillæ are completely differentiated, and their expanded summits are subdivided into many secondary papillæ. The serous glands are also developed, and their ducts open at the usual places. The bulbs have increased in number, and are quite uniformly disposed at the sides of the papillæ; those of the lower tiers, however, are less regular in arrangement and smaller, and lie partly in the mucosa. There is a marked decrease in the bulbs of the free upper surface, though for several months after birth isolated ones still occur there. In the circumvallate papillæ of the adult the bulbs do not appear to have decreased in number on the lateral area, but they have disappeared almost completely from the upper surface. In the adult foliate papillæ bulbs are far less numerous than in early life, and occasionally are wholly wanting. They still occur on the upper area as well as at the sides of the folds.

The bulbs of the circumvallate papillæ always make their appearance first at the upper part of the papilla, the more advanced among them being epithelial in position, while the less mature are to a greater or less extent embedded in the stroma of the mucosa. After the sixth month of fœtal life, the trenches are more or less differentiated, and bulbs begin to appear on the lateral area. In the new-born child and until the fourth month of life isolated bulbs are still present on the upper area of the papilla; at a later period they occur but rarely there. What purpose the temporary taste-bulbs (for such they appear to be) of the free upper surface of the circumvallate papillæ subserve in the embryo is difficult to comprehend. With the appearance of the bulbs of the lateral area they gradually disappear, and, from all indications, perish. By the time the bulbs of the free surface of the papillæ have attained their full development, bulbs in early stages of formation make their appearance on the wall, the lowermost ones being the most elementary. In the present state of our knowledge, there seems to be no better way than to accept Hoffman's hypothesis, that "the bulbs of the free surface perish through the proliferations of the ordinary epithelium." It is not improbable that, after the bulbs have once disappeared from the upper surface, certain altered conditions of the epithelium prevent, save in rare instances, their recurrence there.

From a study of the gustatory papillæ of different embryos it appears that the nerve-fibrils given off from the network beneath the epithelium of the bulb-region of the papilla terminate either as specialized end-organs of taste, or penetrate the epithelium, to all appearances unchanged. The first signs of the future bulbs are to be seen in the basal layer of epithelium and underlying tissue. The ultimate nerve-fibrils which are to constitute the future sensory terminal element, form themselves into loose fasciculi of delicate filaments, the latter becoming more or less modified before penetrating the epithelium. While these changes are taking place in the mucosa there is an increased activity manifested by the contiguous basal cells of the epithelium. These become swollen and elongated, and gradually apply themselves

to and enclose the newly formed terminal structures, of which they constitute the supporting elements.

Griffini's quite recent researches on the regeneration of the gustatory papillæ and taste-bulbs in the rabbit and dog are of especial interest in this connection. From his experiments it appears that after incision of a foliate papilla of the rabbit, the area corresponding to the

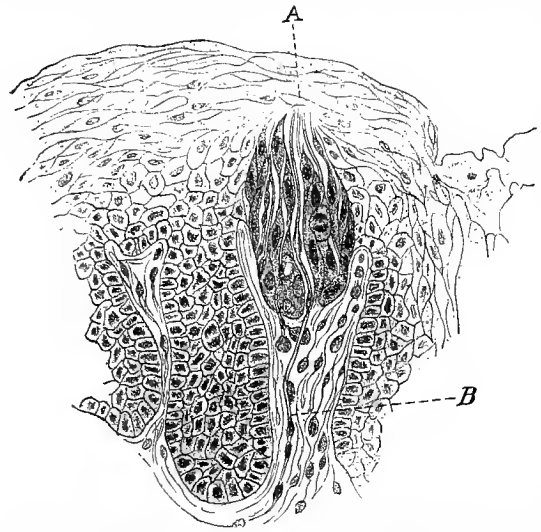

FIG. 606.—Vertical Section through One of the Newly formed Mound-like Papillæ of the Foliate Region in the Rabbit, Fifty Days after the Complete Removal of the Foliate Organ. (Reduced from Griffini; ×300.) *A*, taste-bulb in process of development. *B*, nerve-fibril with many nuclei.

part removed is shortly reinvested with pavement epithelium. Later, from the sixteenth to the twentieth day, a few small hemispherical elevations make their appearance, and these subsequently increase in size and number. During this period, also, many of the injured gland-ducts undergo repair, and communicate with the free surface of the epithelium. Within the secondary papillary processes of the elevations above referred to, taste-bulbs, lying partly in the mucosa and in process of formation, first make their appearance (Figs. 606, *A*, and 607, *T.B.*). Ten days after the complete excision of a circumvallate papilla of the dog, the area of removal is reclothed with epithelium, and the ducts communicate with the free surface. Twenty to thirty days later a slight, and more or less rounded elevation of the mucosa is discernible, analogous to the newly-formed mounds of the foliate organ. The outer enclosing wall of the trench is not regenerated, the newly-formed papilla having the characters of the fungiform type. At the fortieth day (in a single instance only) a few bulbs, situated at the lateral margin of the new papilla, were seen. Following section of the glosso-pharyngeals, the papillæ are changed but slightly, but the bulbs begin to degenerate within twenty-three hours. The taste-cells are first destroyed, disappearing completely by the fifth day; the supporting cells soon after undergo atrophy, and by the twenty-eighth day no bulbs are visible. At the seventy-sixth day after the division of the nerves, bulbs in various stages of formation were observed; but by the two hundred and ninth day their development was still incomplete.

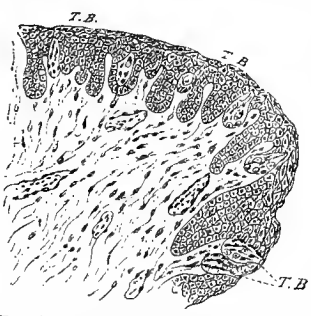

FIG. 607.—Vertical Section through One of the Newly formed, Mound-like Papillæ of the Foliate Region in the Rabbit, Ninety Days after the Complete Removal of the Foliate Organ. (Reduced from Griffini; × 100.) *T.B.*, taste-bulbs in more advanced stages of development.

All of the Mammalia, as far as known, possess gustatory organs. The most primitive form of these structures may be seen in the highly ancestral *Ornithorhynchus*. At the posterior region of the tongue of this animal are two pairs of gustatory areas. The anterior pair lie below the surface in a furrow, the floor of which is invaginated upward into a ridge. The ridges of the posterior pair reach the surface. The ridges of both areas bear taste-bulbs over their entire convexity, and the ducts of serous glands open into the spaces round them. The centre of the ridges is nearly filled by non-medullated nerve-fibres, which radiate outward to end in the bulbs, the latter being developed at the end of long papillary processes. In some of the Marsupialia, notably in *Halmaturus*, *Macropus*, *Petrogale*, and *Dasyurne*, the circumvallate papillæ might very justly be termed gustatory ridges, from their general shape and concealed position. In the arrangement of the bulbs they also resemble quite closely the ridges of *Ornithorhynchus*. In other genera, as *Phalangista*, *Belideus*, *Acrobates*, *Bettongia*, *Phascolaretos*, and *Didelphys*, the posterior papilla follows more closely the type characteristic of higher mammals, while the anterior pair possess structural characters that are common to both the circumvallate type of taste area, and the primitive bulb-bearing ridge. In *Phascolomye*, *Perameles*, and some species of *Didelphys*, all three papillæ follow closely the type common to higher animals. The circumvallate papillæ develop quite independently, and are not, as maintained by some observers, modified fungiform papillæ. In some of the higher forms, however (*e.g.*, in some of the Cervidæ and Bovidæ), it is highly probable that the number of circumvallate papillæ may be increased by direct development from the fungiform type.

In the bandicoots, kangaroos, and phalangers of Australia, the lateral gustatory organs (papillæ foliatæ) may be studied in their simplest form. In *Halmaturus*, according to Poulton, the organ consists of a row of gland-ducts, in the walls of which scattered bulbs are developed. In *Macropus*, *Petrogale*, *Dasyurus*, and *Phascolaretos* the organ is more advanced, the ducts opening at the bottom of depressions. In *Perameles*, it consists apparently of a single epithelial-lined furrow, in the walls of which are several tiers of bulbs. In *Phalangista*, *Belideus*, *Acrobates*, and *Didelphys*, the organs are less simple in structure, and the ducts open at the bottom of the furrows, as in the higher mammals. Between the complex lateral gustatory organs of rodents (in which there is but little to suggest its true origin) and these simple types there are many intermediate stages.

TELLURATES. The tellurate of potassium and the tellurate of sodium are recommended as remedies for the profuse sweatings due to phthisis and other causes. They are given in doses of one-third to one-half grain daily. In some cases this quantity requires to be increased, but generally the second or third dose is followed by a cessation of the sweating. It produces no evident effect on the system and the disease is in no way influenced. It is supposed to produce its effect by an inhibitory action on the nerves of the sweat-glands. In some cases it causes a loss of appetite and nausea, and in some advanced cases the sodium salt has produced a profuse liquid diarrhœa which is very difficult to check. The most serious obstacle to its general use is the persistent garlicky smell which it communicates to the breath and to the perspiration. It is noticed after the second or third dose, but is not very evident to the patient; to the friends, however, it is very objectionable. The salts are generally given at night in the form of pill or in an alcoholic julep. *Beaumont Small.*

TERATOLOGY: A RARE CASE OF HETEROPAGIAN MONSTER. The birth of a well-developed child upon whose anterior surface at the lower portion of the sternum is appended an immatured fœtus, in the vicinage of the umbilicus, constitutes a rare class of monsters to the history of which the attention of the reader is specially invited in this article.

The inert, insensitive, motionless, undeveloped, and deformed fœtus, sustaining a simple vegetative life at the expense of its perfectly matured, self-supporting twin, is a product so dependent upon the active vitality and healthful condition of the latter that, ever since Burdach first called attention to the subject, it has been recognized as a veritable parasite. These parasitic growths present types of configuration so different by contrast with the symmetrical and normal development of the self-supporting twin, or autosite, as this latter has been termed, that Geoffroy Saint Hilaire gave the name of Heterotypia to the entire class, a term derived from the Greek, *ἕτερος*, and *τυπος*, pattern or plan of development.

Grouping together the varieties presented in the sequence of frequency and of asymmetrical conformation, Saint Hilaire arranged these defective products into three orders, to which he gave names that, in their derivative significations, do not appear to have been happily chosen, viz., Hetero'pagus, Heteradel'phus, and Heterod'ymus.

When, for example, the accessory subject consists of only a head and neck, perhaps of a partially developed thoracic limb or two, it constitutes the species which Geoffroy Saint Hilaire designated as his first class of Heterodymus.

If the subject consist of a small, imperfect, accessory appendage, representing an ill-defined pelvis with abortive pelvic limbs, but without head, thorax, or upper extremities, this he called a Heteradelphus.

Now, when the accessory subject presents an imperfectly evolved head and body, an abortive pelvis with rudimentary limbs, both pelvic and thoracic, this exceedingly rare species obtains the name of Heteropagus.

The parasitism of such abortive products is apparent, and their existence as growths, or tumor-like excrescences from the body of a perfect twin would naturally associate them in forming a class of peculiar malformations united by this common recognizable character of *parasitism*. These rudimentary outgrowths of greater or lesser development, and their inconstant attachments to any part of the body of the supporting twin, seem scarcely to justify attempts at a complete classification of all the possible complexities that may occur, so that the writer is inclined to ignore any special effort in this direction which some have endeavored to accomplish. It is sufficient to recognize in such eccentric anomalies the fusion at any region of the autosite's body of abortive developments of any portion of a vertebral axis, or of the dependencies thereof, in the imperfect form of thoracic or pelvic limbs attached to the anterior surface of the perfect child, without separately describing these as so many distinct and invariable conditions of separate varieties of a special class of monsters. It is far more profitable, perhaps, to consider the physiological principles of embryogenesis that may explain such aberrations of development, and to search for the governing influence of that autonomy of cell-genesis which in all these varied and apparent caprices of evolution is found never to infringe the *lex proprietatis* or the *lex topicorum*. Under each of these organogenetic laws it is indeed instructive and significant to note that we never discover dissimilar organs fused indiscriminately into one another unless in their embryonal condition they once pertained to the same blastodermic layer. For example, the liver is never found confluent with the heart, nor shall we ever see the brachial artery anastomosing with the median nerve, because the visceral, organic or hypoblastic layer evolves the one, while the mesoblast and epiblast produce the other of these several organs; such is the observance of the *lex proprietatis*. Again, the conjunction of regional parts always is an instructive illustration of individuality in the life-history of the cell; like cells producing like parts in their proper localities, so that similar parts become always blended with similar parts—thorax with thorax, pelvis with pelvis. Thus, never does the cranium of one monster become united with the pelvis of the other; while the inherent power of the cell to beget its kind always evolves the determinate tissue, structure, organ, or part in its proper locality, wholly independent of any influence or impulse growing out of some centralized emporium of developmental cell force. Thus it is that peripheral distributions of nerves may exist through portions of a parasite's body in which there is present neither spinal cord nor brain, perhaps scarcely an indication of a vertebral axis; and here again we have a perfect fulfilment of the *lex topicorum*.

Classification, if attempted at all in the science of teratology, must rest upon a natural arrangement based upon the laws of morphology and embryology, or we run into an artificial classification of no scientific value. Indeed, complicated irregularities in organic development formed in earlier times an incongruous assemblage of unmeaning events that were indiscriminately recorded without the vaguest conception of an embryological perspective. Anomalies transmitted to us by the graphic pen of illustrious names in science, with accuracy of description and wealth of anatomical details, were marred by the deception of imagination in attempts to explain the multifarious morphological defections in the general drift of endless complexities. No recognition existed in those days of an order of succession in the phases of development that foreshadowed unity in the plan of organization and resolved deflections in structure into one fundamental law. No basis existed then upon which to rest a scientific hypothesis that could reasonably account for eccentricities of development; these, therefore, were frequently referred to some catastrophic revolution in the order of nature. However ingenious may have been the arrangement, through similarity of external appearances, for classification, yet no interpretation could be offered for such deformities, no rule devised for their affiliation, as they were simply regarded as freaks of nature.

The ignorance that prevailed as to the origin of the human embryo, and the consequent non-existence of such a science as organogeny, deprived the teratologist of the means of bringing these abnormalities together into affiliated groups expressive of stages of progressive evolution, and all efforts at their systematic arrangement into orders, genera, and species were left to the arbitrary influences of preconceived opinions.

Little more than sixty years ago, von Baer discovered in the Graafian follicle a protoplasmic element within which the subsequent detection of a germinal vesicle, by Coste, revealed that this bit of microscopic protoplasm was identical with the egg of all animals; that it was in reality the human ovule or germ, holding the unseen mystery of life within itself. This great discovery of the nineteenth century inaugurated the science of embryology and opened a field of inquiry into the fascinating and marvellous researches of embryonal development. The study of embryogenesis and organogeny

detects the law of ontogenetic development, unfolds the archetypal plan of structure, interprets homologies in the vegetative repetition of parts, and thus explains every possible anomaly, whether dependent upon excess or arrest, constructive or destructive development, asymmetrical aberration in the process of bilateral evolution, or deviations in synthetic or diplogenetic malformations. With this science of embryology as the key opening to view what hitherto have been mysteries of teratology, we now are able to relegate to the limbo of traditional demonry and mediæval vagaries the theories that have so long dogmatized upon the subject.

Conversant as we now are with the primordial tracings of the marvellous operations of cell-work within the limits of the germinative area—that title-page of embryonal life—we now can read in the caudal or cephalic cleavage of the primitive streak (*nota primitiva*), or in the yet more complete dichotomy of the neural axis within the blastoderm and vitellus of a single ovum, every form of teratologic manifestation. Interrogating these operations as they occur within this primitive notochord, how indispensable becomes the knowledge of the general homologies growing out of this engaging inquiry, in apprehending intelligently the meaning of parts and interpreting the signification of abnormal anatomy. How readily do we discern those duplicative developments that severally occur amid the *teratа katadidyma* and *anadidyma*, where this primitive streak divides above or below at its cephalic or caudal pole and thereby generates a dicephalus or a dipygus through extreme vegetative polaric growth at either or both ends of the neural axis; producing two heads to one body or one body with two distinct pelves with or without their respective limbs. But again, should a complete longitudinal division cleave the axis into parallel halves, whose formative changes should progress through the serial homologies of two perfect vertebral columns in axial relation to each other, then two organisms would become fused into two more or less symmetrically formed individuals presenting the maximum type of a diplogenetic monstrosity. This, too, would be accomplished not by any deviation or abrogation of the laws of natural evolution, but strictly in conformity with the order and rule and sequence of embryonal formation; and dependent as these organisms would be upon a common vitellus as the proper pabulum sustaining them through their ovular stage of progress, they will become necessarily blended at some contiguous point on the common route toward an ovo-uterine attachment established finally through one common umbilicus. With such a placental prospective the union between such future beings would necessarily be of variable extent; confined alone to the xiphoid appendix or entire sternum or gastric region they would constitute respectively such anomalies as are termed xiphopagus, sternopagus, gastropagus, as the case might be. As monomphalic monsters united, therefore, by their anterior surfaces, and more or less vitally interdependent through organic connections of essential import (that is, an umbilical cord), they would belong to one generic class known as omphalopagus.

Without any great tax upon the imaginative faculty every variety of abnormality reaching out on this line of development, finds its ready explanation.

Pursuing no further than we have done these principles of embryology as elucidating the pathogenesis of development, we shall now discuss that phase of duplex formation which it is the object of this article to explain, and which the reader is prepared to understand.

To appreciate the extreme rarity of this specimen of a heteropagus, or indeed of any of the class of parasite monsters, we must recall the fact that plural births are of themselves very rare. We are told that at the Maternity Hospital in Paris, Madame Lachapelle met with only 444 cases of twins among 40,000 births, which gives but about one twin case to every one hundred deliveries. If this be the ratio of plural births, then how exceedingly rare must be conjoined twins of the diplogenetic order, the most common of all forms of monstrosities? But a monstrosity of any kind is exceptionally of rare occurrence. Unitary monsters do not occur perhaps but thirty times annually among the 30,000,000 births throughout the world.*

Compound monsters are even less frequently met with, while the still more remarkable modification of conjoined twins resulting in the production of a parasite monster becomes so extraordinarily infrequent that but few examples are to be found in the annals of our science, and of these very few the particular instance of a heteropagus such as we here shall describe, is yet more specially rare.

It was in July, 1875, that a summons to Millet Station, on the Port Royal Railroad, afforded an opportunity of examining a monstrosity of the sternepigastropagus parasiticus variety, which is here faithfully represented in different positions in the accompanying figures. Sarah Crittenden Jones, a negro woman, thirty years of age, mother of eight children, had given birth, on June 29, 1875, at Robin's Depot, Barnwell County, in South Carolina, to a well-developed female infant at full term. The uneventful delivery of this child in a natural vertex presentation required no other assistance than that which a monthly nurse had been able to furnish. The child was at the breast nursing vigorously, while the parasite attached to its anterior surface at the lower part of the sternum, encroaching upon the upper portion of the epigastrium, remained motionless, neither breathing nor pulsating in any portion of its frame, presenting the appearance and relationship of a simple growth appended to the otherwise perfect and well-formed body of the sister-twin. The parasitism of this product was the more evident as no excitation of any part of its surface, or of the buccal opening, the only presumably sensitive mucous surface that was accessible, evoked the slightest evidence of reflex action. There being no cerebrum there was no cortical localization for cutaneous or sensorial impressions, and the absence also of any development, or even, perhaps, existence of an automatic nerve-centre in the form of a spinal axis, and the abortive formation of a vertebral theca, with the fragmentary elements of an imperfect cranium served fully to account for this absence of all sensation.

FIG. 608.

The genitalia were scarcely traced out sufficiently to determine the sex, though an urethra and an attempt at the formation of a clitoris seemed to indicate the female sex in conformity with its gemellar origin. It was said that urine had been voided on one occasion, of which we had no proof, but had every reason for doubting, as the urethra was imperforate and there was no evidence of an anus.

The cranium was degraded to an abortive fabric of a few of its basal pieces, as seen in Fig. 608; no brain existed, and the absence of sensorial organs, excepting the external ear, showed a most imperfect facial formation. Of the fourteen bones of this region those were but partially formed which should have completed the

* Ordinary deformities, such as hare-lip, club-foot, sixth finger, etc., are not included as monsters.

orbital and nasal cavities, and neither upper nor lower jaw had reached union on the mesial line.

The thoracic limbs were imperfect also, as only the shoulder girdle and humeri were formed to an equal degree on both sides. The right forearm was complete to

FIG. 609.

the wrist, and both radius and ulna were well developed (see Fig. 609). But on the left side there was no trace of an elbow; the humerus appeared not entirely formed, therefore neither bone of the forearm is recognized on this left side. Here, as is often observed in fetal life, the upper parts of the child's body appear somewhat further advanced than other portions, especially the lower limbs (Fig. 610).

The lower portions of the parasite's frame were conspicuously either deficient or incomplete; for, besides the absence of the genitalia—at least the external organs of

FIG. 610.

generation,—the pelvic limbs suffered nearly complete arrest of development. For example, on the right side it will be seen that there is no vestige of the formation of a right lower limb, the only appearance on that side being the nipple-like protuberance without any osseous formation, as may be verified in two of the above figures.

The opposite side, however, exhibits a partial manifestation of an abortive growth containing something like a bony fabric, but more particularly of a fleshy piece of simple integument permanently curved upon itself—an apologetic effort at the evolution of a left pelvic appendage.

The umbilicus was situated entirely beneath the bond of union, and so removed from ready access that it could not be exhibited in the photographs taken immediately after death, but it pertained specially to the autosite; no real common omphalo-mesenteric connection existed, such as is so easily recognized in almost every diplogenetic monster. Here, on the contrary, the parasite had to be raised up and sustained in this position to bring the navel into view, which was then discovered to be on the abdominal surface of the perfect child; no direct intercommunication obtained between the abdominal cavities of the two organisms. The sister child had during its life enjoyed perfect health, taking and assimilating its nourishment well, as was shown by the regularity of its alvine dejections.

The absence, then, of direct placental support indicates the true parasitic character of this unnatural formation; a most imperfect organism that could only sustain a vegetative existence so long as the life of the perfect twin continued to nourish it, growing slowly as might some adventitious excrescence which appropriated metabolically whatever nourishment it derived from the parent organism.

This kind of life was prolonged through three months, for the expenditure incident to the demands of so conspicuous a growth, so to speak, exhausted rapidly the best directed activities of an otherwise healthy and perfect child. During this period no phenomenal occurrence claimed any special notice; the parasite presented the same inert, motionless, insensitive, vegetative existence, neither secreting nor eliminating any product which careful observation could discern. We must always regret that an unforeseen casualty interdicted the dissection of this specimen, which might have revealed yet greater deviations of evolution of such internal organs as might have been found, yet the contemplation of these life-like representations perpetuated in such well-executed figures as are here appended to its history, will certainly satisfy more than a simple curiosity, as the reader is in the presence of one of the rarest of heterotypic monsters.

Middleton Michel.

TETANUS, BACILLUS OF. The etiology of traumatic tetanus has been thoroughly established by Kita-

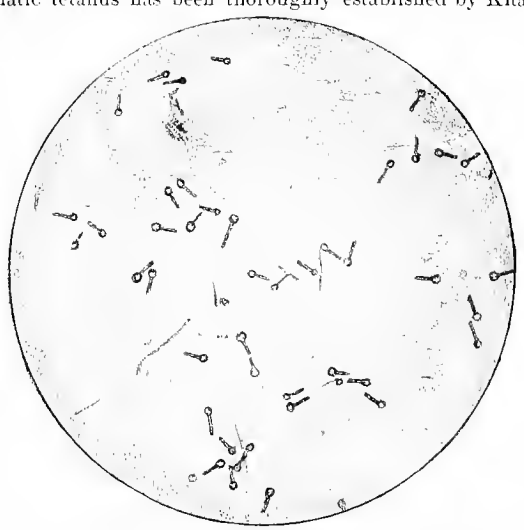

FIG. 611.—Bacillus Tetani. Preparation made from a very virulent gelatine culture in hydrogen. 1,000 times. (From a photograph.)

sato.* The organism first observed by Nicolaier, but not

* Ueber den Tetanusbacillus, Zeitschrift für Hygiene, etc., 1889, vol. vii., p. 225.

obtained in pure cultures by him, was isolated by a special method by Kitasato, and subsequently by several others with Kitasato's method. I also have obtained it in this way.* The method consists in smearing the pus from the wound of a human being, or animal, suffering from tetanus, upon the surface of an oblique agar tube, which is then placed in the incubator at 35° to 37° C. In order to produce the disease in the first place, it is only necessary to inoculate an animal under the skin with a small amount—several pinches of the forceps—of rich garden earth ; † barren sand or wood mould will not produce the disease. Cover-glass preparations from one of the oblique agar tubes described above, made in twenty-four hours, show a number of different organisms, among others the peculiar drumstick bacillus of tetanus. These latter, being exquisite anaërobic organisms, do not grow on the surface of the agar ; but those of them which are contained in the pus go into the spore formation. If the culture is kept in the incubator for two days or more, the spore-bearing bacilli will be found in larger numbers than after twenty-four hours. These spores are very resistant ; they stand a temperature of 80° C. for an hour or more, and the method of isolating them depends upon this quality.

The oblique cultures above described are heated in a water-bath at 80° C. for three-quarters of an hour or more, and this kills all the vegetative cells which are present, and often kills all the spores of the organisms other than tetanus which happen to be present. After heating, inoculations are made in flat, round, sterilized vessels containing sterilized agar or gelatin previously melted. These vessels are of peculiar construction, having a narrow inlet tube and a wider outlet, both plugged with cotton previous to sterilization. A series of these vessels are inoculated, as for making Esmarch tubes or plates, and the narrow tube connected with a hydrogen apparatus, and hydrogen allowed to bubble through till all the oxygen is driven out, when the outlet and inlet tubes are melted off in a Bunsen burner in the order given. Colonies appear in about ten days in gelatin anaërobic plates of this kind, and in one or two days in agar. The vessels are then cracked open, and the colonies transplanted to deep agar or gelatin tubes. I have substituted for this apparatus a modified form of the Liborius hydrogen tube, which can be made without much trouble. The tube I use is made by blowing a small hole in the bottom of a test-tube, and melting on a small glass tube ; this tube is bent up against the side of the test-tube for about two inches, and is then bent out at right angles. These tubes are used just in the same manner as Kitasato's plates, the top of the test-tube and the narrow tube being melted off after the hydrogen is run through. To facilitate this sealing of the tube, the test-tube and the narrow tube should be drawn out somewhat before the hydrogen is bubbled through. After the colonies appear a file scratch is made, and a piece of red-hot glass rod applied so as to crack the test-tube open at any point desired. Stab-cultures must be made by inoculating into tubes containing a large amount of gelatin or agar ; or better still, by inoculating a tube containing a smaller amount of agar, and pouring the melted contents of another tube on top, thus excluding the air. The colonies have a small, dark centre by transmitted light, with a fluffy zone around. Fresh cultures of full virulence liquefy gelatin but not agar ; old cultures, or those which have lost virulence, do not liquefy gelatin. The bacilli grow out into long threads at ordinary room temperature, but form the characteristic spores at 35° to 37° C. in the incubator in about twenty-four hours. They then appear as short, fine rods, with a large round knob on one end, the knob constituting the glistening, resistant spore. The bacilli have independent but slow motion ; flagella have been demonstrated. They stain by Gram's method. *Meade Bolton.*

TEUCRINE. This name is given, by Professor von Mosetig-Morhof, to an extract of *Teucrium scordium* which he recommends for the treatment of local tuberculosis. In announcing his method of treatment at the Medical Club of Vienna, February 1, 1893, he stated that for five years he had been searching for a substance which, when introduced into the organism, had the property of provoking an hyperæmia of the morbid tissue. Teucrine was found to possess this action, and he reported a large number of cases of tuberculous abscesses, enlarged and diseased glands, lupus, and actinomycosis in which it was used with very satisfactory results. In the diseased tissue an acute inflammatory action is set up which is followed by a breaking down and destruction of the affected tissue. In abscesses the chronic became converted into acute in twenty-four hours, and could be treated as ordinary acute suppuration. Generally speaking, the chronic abscess could be cured in this way in eight or ten days, providing it was not connected with diseased bone. Dr. Mosetig has watched the cases for months, and no recurrence has taken place. In glandular disease the enlarged glands are rapidly absorbed if the disease has not advanced. The therapeutic effects in these cases vary with the presence or absence of caseous degeneration. When it is present the injections give rise to an acute inflammatory action ; when the disease has not advanced to that stage the material becomes rapidly absorbed.

The reaction produced by the subcutaneous injection is both general and local. The constitutional symptoms, whether the system be healthy or diseased, show themselves as a rise in the temperature, which is often preceded by a chill, and may last for ten or twelve hours ; the patient, however, does not feel ill, the skin is moist, the appetite is preserved, and the secretions are unchanged. The local symptoms, when there is no disease, consist in a slight redness and swelling about the site of puncture, but when there is diseased tissue a very active hyperæmia is induced, and the swelling, pain, etc., are in accordance with the extent of the disease. The method of employing the remedy is very simple : three grammes of the fluid are injected in the neighborhood of the disease with an aseptic syringe.

The extract is prepared from the dried plant by lixiviation with hot water. The liquid obtained is evaporated to the consistence of honey, it is then washed with alcohol and concentrated until its specific gravity reaches 1150. It is a brownish-black liquid with an acid taste and an odor that is somewhat like cabbage. It has an acid reaction and is soluble in water. Taken internally in doses of eight grains, no other effect was noticed beyond a tonic action on the stomach and appetite.

Teucrium scordium, the water germander, or wood sage, is a member of the Labiatæ, or mint family. It is a common wild plant in Southern Europe, and is also found in England and other temperate countries of Europe. It is a creeping marsh plant, with a disagreeable garlic-like odor when bruised. In this country the genera is represented by a single species, the *Teucrium canadense* L.

The various species have always had a reputation as remedies of some value, but have long been discarded from the Materia Medica. As an antidote for various poisons they were much esteemed, and were also used as an anthelmintic. The *Teucrium scordium* also has a local value as a remedy for the early stages of hemorrhoids. Dr. I. H. Brinton (*Therapeutic Gazette*, January, 1892) publishes a paper in which he praises it for this condition, and states that it affords rapid relief to pruritus ani arising from this cause. He administers the powdered leaf in doses of ten or twelve grains, three times a day, half an hour before meals. It acts as a stomachic and stimulates the appetite, resembling pepper in its action. The beneficial effects are noticed in ten or twelve days and are very satisfactory. Other observers have recommended a local application of an ointment prepared from the extract.

Beaumont Small.

THIERSCH'S SKIN-GRAFTING. The chief value of this method of skin-grafting lies in the fact that it prevents the deformities that would result from the natural healing of the wound by granulation and the subsequent contraction of the scar. A second advantage, in some cases one of extreme importance, lies in the fact that even very large surfaces may be healed promptly.

The grafts consist of shavings of the superficial portions of the skin removed by a razor, and are applied so as completely to cover a wound surface which is free from granulations and presents only normal tissues. A special dressing is applied. The grafts adhere, and by the end of two days they are receiving blood from their new site. The formation of granulation tissue ceases, the wound is healed, and no contraction takes place. A soft, pliable integument is provided, of good vitality and well able to withstand the wear and tear to which a cutaneous surface is exposed. In removing the grafts, the razor does not cut deep enough to include the hair bulbs. No hair will grow from the grafts. Grafts from a hairy thigh may be planted upon the face or hands without fear of transplanting hairs.

This form of skin-grafting has a very wide sphere of usefulness. Where there is extensive loss of skin in the vicinity of a joint, as may follow a burn or other injury, it will entirely prevent cicatricial limitation of motion. Similarly, where the healing of a wound by granulation would result in a distortion of soft parts, it will prevent the deformity. Large areas of malignant disease may be freely removed and rapid healing secured. Thus, extensive areas of tuberculous skin may be dissected off, leaving a healthy wound surface, and the defect covered at once by grafts. Cancerous breasts may be radically removed, regardless of flaps, and the large raw surface, consisting of fat, muscle, and periosteum or bare bone, all covered by a good integument. A thick graft contains a sufficient supply of anastomotic vessels to allow the graft to bridge over a slight interval, independently of nutrition from beneath. For example, after a burn involving the outer half of the little finger, causing superficial necrosis of the bones and opening the first joint, the author applied rather a thick graft so as to bridge over the interval from bone to bone and close the joint. The graft retained its vitality perfectly, and the joint is neatly closed and capable of a little motion. Congenital deformities which could be relieved by making an incision, drawing the edges of the skin apart and covering the wound surface with integument, can be remedied by this method. In cases where scar contraction has already caused deformity, the scar tissue should be freely and completely excised, the parts brought into their natural position, retained by splints if necessary, and then the wound covered by grafts. If the faulty position has not caused grave damage to the deeper structures, deformity can be relieved and lost function restored. In short, Thiersch's method of skin-grafting finds application wherever it is desired to interpolate an area of soft and healthy integument and normal tissues can be provided for its reception.

FIG. 612.—Represents a microphotograph of a transverse section of a skin graft taken from the upper arm.

Certain details of the operation are of the first importance. The excellence of the results obtained and the extent of surface that can be covered in a given space of time depend much on the skill and experience of the operator, but the operation is not a difficult one, and no surgeon should hesitate to undertake it.

The following is a condensed description of the technique which the author has chiefly used:

As was said above, the surface to be grafted should be one of normal tissues. An operative wound usually needs no preparation for the reception of the grafts. A granulating surface may be washed every other day with soapsuds and with sublimate solution and dressed with iodoform gauze saturated with balsam of Peru, until it presents a smooth, firm, and red surface. Preparatory to operation it may be dressed with sublimate gauze. If the patient has syphilis, it is well to give iodide of potassium or mercury for a week or two before operating; otherwise the grafts are liable to perish.

If there is freedom of choice as to the place from which the grafts shall be taken, the thigh should be chosen. The day before operation it should be shaved, scrubbed with soapsuds, and with 1 to 1,000 sublimate solution and wrapped in sublimate gauze. Shortly before operation it should be washed again with sublimate solution. Time will be saved at the operation if two sublimate towels are applied as follows: Let the lower edge of one come below the knee, wrap it round the limb, and secure its lower border by a sublimate gauze bandage round the knee; let the upper edge of the other towel encircle the thigh as high as possible and secure it similarly by a bandage. When the second towel is turned up and the first down, the thigh is at once exposed and is neatly bordered by sublimate towels. Wrap the thigh in wet sublimate gauze, and secure the towels over it.

Select a razor ground flat on one side. It is well to be provided with two. The edge must be very keen. For scraping away granulations, any instrument with a blunt edge will serve. Cicatrized borders can be removed by the Volkmann scoop or the knife. A probe aids the fingers in nice adjustments of the grafts. A pair of rough bathing mittens are a help to the assistant in getting a proper grip upon the skin. The mittens should be boiled or baked before using. The razors may be soaked in five per cent. carbolic solution for fifteen minutes and dipped in salt solution before being used.

During the operation the only solution to be used is one of sodium chloride of the strength of 6 parts to 1,000 of water. This is the so-called "physiologieal salt solution" and does a minimum of damage to the grafts. A large tin-pail of this solution should be boiled for an hour, and then kept at blood heat by being set in a vessel of larger size and surrounded by water which is kept lukewarm. At the operation four sterilized bowls should be filled with this solution, one for the hands, one for sponges, one for gutta-percha strips, and one to receive the grafts as they are cut.

Prepare strips of gutta-percha tissue three-quarters of an inch wide, and long enough to reach across the wound and lap over on each side. These should be washed with soap and water and with sublimate solution and placed in salt solution before being used. Sublimate gauze and sublimate gauze bandages should be wrung from salt solution to serve as the inner dressing. Sponges should be taken from carbolic solution and wrung out in salt solution for use.

Much depends on the position of the patient on the operating-table. Build up the table by pillows placed beneath the body and head, and a smaller prop under the foot, so as to elevate the patient half a foot above the table, and allow the thigh to form a bridge, and thus be readily got at from all sides. If the surface to be grafted is on an extremity, it should be suspended vertically, in order to check hæmorrhage and to permit of free handling without altering the position of the limb.

Unless the operation is a very trifling one, and in a patient of especially good endurance, ether or chloroform should be given.

This operation is performed not with antiseptic, but with aseptic, precautions. The field of operation must be sacredly guarded from the ingress of germs. The hands must be scrupulously disinfected with soap and water and with sublimate solution, and the operative field surrounded by bichloride towels. The first step of the operation is to remove any abnormal tissues. Granulations may be scraped away and cicatrized borders cut away or removed by the Volkmann scoop. Then wash with salt solution and apply at once a compress of gauze. Bind it on, or have an assistant maintain the pressure. Next throw back the towels from the thigh, take off the gauze, let an assistant grasp the skin with both hands and draw it tense transversely. Place the thumb of the left hand

on the tense skin at one end of the thigh, to make a little longitudinal tension, and apply the razor to the skin at a moderate angle. Make a short sawing motion, and at the same time increase the angle at which the razor meets the skin until the edge bites into the skin and begins to raise its upper portion. This angle is then maintained, and with the continuance of the short sawing motion a graft is cut whose length is limited only by the length of the thigh. The tough corium is of great assistance in preventing the razor from cutting too deep. In width the grafts will vary from half an inch to two inches, according to the locality from which they are taken and the skill of the operator and his assistant. Very wide grafts may be got from the comparatively flat surface over Scarpa's triangle. As fast as cut, the grafts should be dropped into a bowl of salt solution.

The manner of cutting the grafts is illustrated in Fig. 613.

In about ten minutes oozing will have ceased, the compress may be removed, and the grafts applied. It will be found that they have curled, with the cut surface inside. To uncurl them, place one end on the surface to be grafted, uncurl it, and keep it uncurled by pressure with a finger of the left hand. The whole graft may now be uncurled by making a rapid to-and-fro motion with a finger of the right hand, and carrying it along the entire length of the graft. The graft is now flat upon the surface and can be moved about with the fingers or probe. The grafts should be made to meet or overlap each other, and also the surrounding skin. Overlapping does no harm, for the superficial edge of a graft will die from lack of nutrition and come away, leaving a mere line of union visible. If not enough grafts have been cut, more should now be cut and applied directly. When the whole surface has been covered, douche it gently with salt solution, and apply the gutta-percha strips in the following manner: Lay one end upon the sound skin at one side of the wound and secure it by a thumb, then, with a winding motion, lay the strip across the wound and out upon the sound skin beyond. In this way the strip is laid on without in any way disturbing the grafts. Let the next strip slightly overlap the first. Continue imbricating each upon the last till the whole surface is covered by the tissue. If the surface is on an extremity, take a wet gauze bandage and apply a snug spiral to hold the tissue and grafts firmly in place. Next apply damp salt gauze, a sheet of gutta-percha tissue to maintain the moisture, sublimate gauze, cotton, a bandage, and a splint suitable to the region. The surface from which the grafts have been taken may be covered with gutta-percha tissue and moist gauze. This is a particularly comfortable dressing, but any simple dressing will answer.

It is advisable to change the dressings every two days for the first eight days. At the end of six days the gauze had best be allowed to dry, by omitting from the dressings the sheet of gutta-percha tissue. This will obviate too great maceration of the horny layer of the grafts, and fit them sooner to withstand the wear and tear of exposure. At the end of ten days the gutta-percha strips are no longer needed. If there are any spots of granulation from faulty adjustments of the grafts, they had best be covered with yellow adhesive plaster. If the surface is uniformly covered with grafts, it needs only to be protected for a few days by a piece of cloth spread with lanoline or vaseline.

FIG. 613.—Taking the Grafts.

FIG. 614.—Shows the Condition of the Knee (in Case C. A.) in May, 1892.

To illustrate the value of Thiersch skin-grafting, the citation of a single case where it was particularly called for and achieved its fullest function will suffice.

In August, 1889, C. A——, a girl, aged twelve, met with an injury by which a very large skin flap was torn from about the right knee. It involved the inner side of the thigh, knee, and leg, and extended outward beyond the ligamentum patellæ and crest of the tibia. In the following November I grafted the surface. Her general condition was poor, and I did not think it wise to continue anæsthesia long enough to cover the large area completely; a portion was only partially covered with grafts, and intervening spaces about half an inch wide were left to cicatrize. In four weeks healing was firm. The limb had been in splints for more than a third of a year, and, when they were left off, there was scarcely any motion at the knee. A cylinder of cloth, stiffened by a covering of oiled muslin, was spread with vaseline and suspended about the limb for a few weeks to guard it from harm. Exercise of the limb was encouraged, and occasionally moderate force was used to aid flexion. In March, 1890, the knee came to a right angle, and she went upstairs one foot after the other. Freedom of motion became progressively greater until it was as perfect in the right knee as in the left, and the limb as useful as before the injury. The accompanying Figure (614) is from a photograph of the case taken in May, 1892, and shows how the grafted area offers no hindrance whatever to complete flexion. *Theodore Dunham.*

THILANIN. This title is given to a compound of sulphur and lanoline, which is said to contain three per cent. of sulphur, but whether in combination with the cholesterine or with the fatty acids is undetermined. It is a yellowish-brown, unctuous body of the consistence of lanoline. It was introduced by Dr. Edmund Saalfeld, at the third Congress of the German Dermatological Society, as being devoid of any irritating properties and useful in cutaneous affections. The author had used it with success in acute, subacute, and chronic eczemas, acne, and various forms of skin disease. Its further use has not been reported upon. *Beaumont Small.*

THIOL. This sulphur compound has been introduced as a substitute for icthyol, to which it is closely allied. Icthyol is prepared from fossiliferous remains which are rich in sulphuretted hydro-carbons and complex organic compounds. Thiol, which is described as an artificial icthyol, is prepared by treating with sulphur the hydro-carbons, with a specific gravity between 0.890 and 0.900, that are obtained from coal tar. The latter differs from icthyol by the absence of much organic matter that supplies its objectionable qualities, their presence, it is claimed, being of no therapeutic value. The method of preparation consists in the sulphuretting of the hydro-carbons and then acting on them with concentrated sulphuric acid. This, when cooled, causes the impure thiol to separate in a distinct layer, which is drawn off, purified by washing to remove excess of acid, and then evaporated to an extract—*thiolum liquidum*, or to complete dryness—*thiolum siccum*.

Liquid thiol is a thin, brownish, neutral liquid, with a specific gravity of 1.080 to 1.082 at 60° F. It has a feeble bituminous odor, not disagreeable. It forms a clear solution with water, especially if glycerine be added. It is not very soluble in alcohol or ether. Aqueous solutions froth abundantly when shaken ; they are not affected by the addition of strong alcohol, but soda, dilute acids, or metallic salts cause a precipitate. Dry thiol, which forms forty per cent. of the liquid form, is a dark-brown or blackish mass, sometimes formed in scales, which, when heated, burns away entirely, leaving no residue. The advantages claimed for thiol over icthyol are, that it is really a purified form of the latter, that it is devoid of the disagreeable odor, and does not stain the linen or clothing, is less irritating, and more definite in composition. It, however, does not contain numerous hydro-carbons and combinations of sulphur which are present in icthyol and are supposed to be indispensable to it as a therapeutic agent.

The therapeutic value of thiol is said to be due : (1) to a contractile effect upon the vascular system by virtue of which its application is of value in conditions of the skin due to or associated with dilatation of the vessels and capillaries, as in hyperæmia, erythema, and inflammatory processes generally ; (2) to a desiccating and "horn-forming" action upon the skin, which is of importance in the treatment of moist, papulous diseases, and wounds, burns, etc.; (3) to a certain antiseptic power ; (4) to an action in promoting the absorption of exudations when locally applied. It has been used with success in eczematous affections ; in acute, moist, inflammatory processes, as erysipelas, herpes, herpes zoster, acne ; in the ulcerative processes of syphilis and tuberculosis, and in simple ulcers. In articular infiltrations and œdema, due to rheumatism and other causes, the application of thiol hastens the absorption and dispersion of the fluid and inflammatory deposits. In gynecology this same action is made use of in para- and peri-metritis accompanied by exudation. Endometritis, erosions of the os, and similar conditions are reported to be rapidly improved by this treatment.

Although the pure drug may be applied without causing any irritant action, a ten per cent. preparation is generally sufficient for all purposes. The powder may be combined with powdered starch ; or aqueous or glycerine solutions may be prepared. For wounds a five or ten per cent. solution in collodion is very serviceable. An ointment may be made with vaseline or lanoline.

Internally it is without toxic action, and unirritating to the stomach or intestines. For inflammatory diseases, and in gynecological practice, its action is increased by internal administration in addition to its local use. The dose is one and a half grain, which may be repeated up to five times a day. It is given in sachets, in pill form, or in solution in wine. *Beaumont Small.*

THIOPHENE. C_4H_4S. This is a sulphur-holding hydro-carbon, contained in coal-tar benzine. In the pure state it is a colorless, clear, volatile oil, boiling at 184° F., of slight odor, and will not mix with water. Thiophene itself is not employed as a therapeutic agent, but two preparations have been introduced—*sodium thiophensulphonate* and *thiophene di-iodide*.

Sodium thiophensulphonate, $C_4H_3SNaSO_3$, is a white crystalline powder, containing thirty-three per cent. of sulphur, and having a slight but unpleasant odor. Used as a dusting-powder, or applied as an ointment, ten per cent., with equal parts of lanoline and vaseline, it has proved of much service in all forms of prurigo. A lead salt has also been prepared and used with success in the same disorder.

Thiophene di-iodide, $C_4H_2I_2S$. In this salt two atoms of hydrogen are replaced by two of iodide; it contains seventy-five per cent. of iodine and 9.5 per cent. of sulphur. It forms in fine crystalline plates, insoluble in water. The di-iodide has been proposed as a substitute for iodoform, as it has a less unpleasant odor. It has been employed in all conditions in which iodoform is used with success, and experiments have shown that it possesses an antibacterial power very similar to the older drug. It has not yet received much attention.

The pure powder is used by dusting in the wounds, and covering with ordinary gauze, or a medicated gauze may be prepared with the following solution : thiophene di-iodide, fifty parts ; alcohol and ether, of each five hundred parts ; glycerine, ten parts. It has a slightly aromatic, and not disagreeable odor, which is much less persistent than that of iodoform. No toxic effects have been detected after the free use of the powder.

Beaumont Small.

THIOSINAMINE. This long-known chemical compound has been recently introduced as a drug possessing valuable therapeutic properties. It is obtained by the action of alcohol and ammonia upon the ethereal oil of mustard, which forms a basic compound with the following formula, C_3H_6, NH, NH_2, CS. It forms in colorless and odorless prismatic crystals, having a bitter taste, and is readily soluble in water, alcohol, and ether. The solution should not affect test-paper.

Thiosinamine has attracted attention on account of its reputed resolvent action upon scar tissue. When injected into tissue causing deformity and disability by contracture, it is said to produce a softening and relaxation which allows the part to become free and pliable. Numerous cases of fingers and limbs that were beyond the use of the knife, are reported to have been almost perfectly restored. This effect was announced by Dr. H. v. Hebra, Jr., of Vienna, in 1892, at the International Congress on Dermatology. He recommends that a fifteen per cent. alcoholic solution be prepared, and two injections a week be used, of two to four drops. No effect is produced upon the system, but the tissue rapidly becomes soft and relaxed. It has also been used with success for the purpose of relaxing the cicatricial tissue of urethral strictures. (*La Semaine Médicale*, March 3, 1893.) In three cases the patients were able to pass their urine freely on the day following the first injection ; the stricture, however, recurred upon the cessation of treatment. It has also been used in gynecological practice (*La Semaine Médicale*, February 3, 1893) to relieve the distressing symptoms arising from the effects of peri-metritis and inflammatory troubles about the appendages. Two and a half to ten drachms of a fifteen per cent. solution were employed, and a decided improvement noticed in all the cases treated. In addition to its action on cicatricial tissue, it causes a decided increase in diuresis and diaphoresis, and exerts a powerful tonic effect upon the system, in consequence of which it is thought to have a beneficial resolvent action upon local tuberculosis. Upon chronic enlargement of lymphatic glands its effect was very marked. In a number of cases of lupus it was noticed to exert a beneficial action ; a few injections changed the aspect of the disease, the nodules became smaller, the diseased tissue and ulcers improved, the edges became flat, and the surface healed in a few weeks. No complete cures were effected, but improvement was noticed in every instance. The injections were made in the back. No constitutional effect followed the injections, but a local reaction set in after a few hours, causing redness, tension, and swelling of the affected part. *Beaumont Small.*

THOUGHT-TRANSFERENCE.—Since the foregoing article (by Dr. Morton Prince) on Thought-Transference was written, various series of records have been published which materially increase the strength of the evidence for Thought-Transference. We shall mention the most important of these in the order of their publication, not attempting to summarize them all, and shall also notice some other series of which no accounts were given in Vol. VII. of this work.

In Part XII. "Proceedings S. P. R.," Professor Charles Richet published a detailed account (pp. 18–168) of his own experiments, under the title "Relation de diverses expériences sur la transmission mentale, la lucidité, et autres phénomènes non explicables par les données scientifiques actuelles." In this article Professor Richet apparently goes beyond the acceptance of mere thought-transference, which he regards only as a special case of a more general phenomenon which he calls by the name *lucidité*—implying, by this term, the existence of some faculty of knowledge which is independent of our normal faculties of knowledge. In the same "Proceedings S. P. R.," Part XII., is an article confined to "Experiments in Thought-Transference," by Messrs. A. Schmoll and J. E. Mabire, these being a continuation of some experiments reported in the previous number. These experiments were conducted with a small circle of friends; "all the investigators," say the authors, "were aware of the scientific scope of the attempts, and vied with each other in their zeal in excluding all source of error and in obtaining conclusive results." Their experiments were chiefly with diagrams and cards, the former trials being more numerous and more successful. We reproduce four consecutive trials made on March 4, 1887, and two selected trials on April 8, 1887.

In the above series the experiment began apparently by the percipient's seating himself blindfolded in an arm-chair in the corner of the room. The drawing was placed on a table in the middle of the room and the persons present directed their looks toward it, facing also in the general direction of the percipient's back.

"The percipient drew nothing while seated in the arm-chair. If at the end of ten or fifteen minutes he announced that he saw a figure, the original was hidden and he was requested to come to the table and draw what he had seen. He then did so under our eyes, but in the midst of perfect silence. If the reproduction thus obtained bore more or less resemblance to the original, the percipient was replaced in the arm-chair and the experiment was continued; only in the most successful cases did this repetition not take place. If, on the contrary, the figure produced by the percipient was without any resemblance

March 4, 1887.

Percipient.	Agents.	Original Drawing.	Result.
M. Mabire.	Mme. D. Mlle. Marthe. Mlle. Jane. Mme. Schmoll. M. Schmoll.		"I see a Y," said M. Mabire at first. Toward the end of the experiment the image had changed a little, and M. Mabire drew the following figure: Duration of experiment, 10 minutes.
Mlle. Jane.	5. M. Mabire in place of Mlle. Jane.		"I see a triangle, with its base below. The triangle appears to me to be filled up; but the darkness, very pronounced at the angle, disappears at the base—which is itself not represented at all." Then Mlle. Jane drew this figure: Duration, 12 minutes.
Mme. D.	5. Mlle. Jane in place of Mme. D.		"I see something like a flower with four extended leaves." "Now, there are two ellipses placed together horizontally, like an 8 lying down; a descending stroke separates them." Duration, 12 minutes.
Mlle. Marthe.	5. Mme. D. in place of Mlle. Marthe.		1. "An extended curve, convex upward." 2. "Three curves, horizontally united, and a white spot above." The following are the two drawings made one after the other: 14 minutes.

April 8, 1887.

Percipient.	Agents.	Original Drawing.	Result.
Mlle. Louise.	5. (plus Mr. Myers).	 This figure was drawn by Mr. Myers.	At the end of a few minutes, Mlle. Louise said: "I see three fish on a skewer." Not being well understood, she explained: "Three fish held by a skewer, that is as they are sold in the fish markets; but everybody knows that!" Then she took off her bandage and drew: Mlle. Louise.	5. (plus Mr. Myers).		

to the original, it was passed by, and the trial regarded as a failure."

Later on, the percipient made his drawing where he sat in the arm-chair, and still later the match used for sketching the original designs, which as making "no appreciable noise," had been chosen "in preference to a pen," was replaced by "a sable-hair brush." The whole series of experiments adds distinctly to the evidence for thought-transference, unless we impugn the good faith of the investigators; who seem to have imposed more and more stringent conditions upon themselves for the purpose of rendering their experiments more evidentially valuable.

The next batch of evidence comes from Professor and Mrs. H. Sidgwick and Mr. G. A. Smith, whose experiments were recorded in Part XV., Proceedings S. P. R. The general results are summarized by the writers as follows, in the beginning of their paper:

"The experiments in thought-transference about to be described have been carried out with four different percipients while in the hypnotic trance, Mr. Smith, who hypnotized them, being the agent. The experiments were usually directed and arranged by Mrs. Sidgwick, who also took the notes which form the basis of the present paper. On two or three occasions, however, she was absent and her place was taken by Professor Sidgwick, who was also present on most other occasions in July and August.

"Most of the experiments were in the transference of numbers of two digits, Mr. Smith looking at the numbers and the percipient guessing them. The number of experiments of this nature tried with Mr. Smith in the same room as the percipient was 644, of which 131 were successes; and the number tried with Mr. Smith in another room was 228, of which only 9 were successes. In these numbers an experiment in which two percipients were at work at the same time is counted as two. By a success we mean that both digits are correctly given, but not necessarily placed in the right order. Of the 131 successes with Mr. Smith in the same room the digits were reversed in 14; and of the 9 successes with Mr. Smith in a different room the digits were reversed in 1. We had no numbers above 90 among those we used. If the percipients had been aware of this the probability of their guessing the right digits in the right order in one trial by pure chance would have been 1 to 81, and the probability of their guessing the right digits in any order half that. But, as at different times they guessed all the numbers between 90 and 100, we believe that they were not aware that our series stopped at 90, in which case their chance of being right in a single guess was 1 to 90. No one will suppose therefore that 117 complete successes in 664 guesses was the result of chance. Good days and bad days alike are included in the numbers given, though, as will be seen in the sequel, on some days no success at all was obtained. It was clear that the power of divining the numbers was exceedingly variable, but whether the difference was in the agent or the percipient, or on what circumstances it depended, we have so far been unable to discover.

"Eight persons, at least, besides Mr. Smith, tried to act as agents, but either failed to hypnotize the percipients, or to transfer any impression. Nor did others succeed in transferring impressions when the hypnotic state had been induced by Mr. Smith. Mr. Smith himself did not succeed except when the percipients were hypnotized."

The numbers used belonged to a game of loto, and in some of the experiments they were drawn out of a bag by Mr. Smith, "between his finger and thumb, which effectually concealed the figures, and placed in a little box, about an inch deep, which he held in his hand with its back to T. T.'s eyes were apparently closed, and he kept his head very still, and we ascertained by experiment that he would have had to move it several feet to see the number." In other experiments a curtain separated Mr. Smith from the percipient, or Mr. Smith stood behind the percipient. Sometimes the number was drawn from the bag and handed to Mr. Smith by another witness. The whole series of experiments are classified very carefully, with full information as to the positions of agent and percipient. When two subjects, P. and T., were both hypnotized, it was found that the guesses of P. influenced those of T. to a certain extent—unconsciously as far as T. was concerned; and the authors concluded that "for evidential purposes in psychical research no reliance can be placed on the fact that a person—whether hypnotized or not—is entirely unaware that an impression has reached him through his senses, if by any possibility it could so have reached him. It is, therefore, necessary to examine the experiments dealt with in this paper with anxious care, in order to see whether there was any possible channel of sense through which the agent's impression could have reached the percipients.

"The eye is, we think, absolutely excluded. There were a sufficient number of successful experiments with Mr. Smith behind the percipient and with the percipient's head covered over, to make it unnecessary to consider the various possibilities of careless handling of the numbers, reflection in the cornea, or changing facial expression and gesture.

"The sense of touch may also, we think, be regarded as excluded. There was never any direct contact between agent and percipient, except in one or two cases where it was purposely tried and did not produce success; and it seems absurd to suppose that vibrations of the floor caused by rhythmical movements of the agent, of which he was himself unconscious and which were invisible to others, can have been powerful enough to affect the percipient.

"We are reduced, then, to the sense of hearing."

The question whether any indications could have been received by the percipient through the' sense of hearing, even assuming hyperæsthesia on the part of the percipient, is discussed in much detail, and the authors conclude that the conditions of success "were, at any rate, independent of unconscious auditory indications."

In Proceedings S. P. R., Part XVII., Baron von Schrenck-Notzing, M.D., Munich, has given an account of "Experimental Studies in Thought-Transference." He divides his experiments into two series—experiments in thought-transference with drawings, and experiments in guessing objects, persons, etc., thought of. The second series is hardly of sufficient importance to summarize here. In the first series are recorded twenty-six experiments with drawings. In one of these trials the percipient drew nothing, getting no impression, and in the other cases, regarded as complete failures, the drawings are not reproduced by the author. The remaining twenty-two drawings are given here, *O* representing the original drawing, and *R* the reproduction by the percipient.

In the following five trials, Graf S., aged twenty, was percipient. In 1 and 2 Dr. Notzing was alone agent; in 3 and 4 Baron von Welden assisted as agent; in 5 Baron von Welden was alone agent, Dr. Notzing being a passive witness. The method of experimenting was as follows: Graf S. sat in an arm-chair while the agent went into the next room, and the door being closed, made the original drawing. The agent returned with the drawing, holding it so that "it was absolutely impossible for the percipient to see anything of it," and took his seat almost directly behind the percipient (the author gives a detailed plan of the rooms), and thought as vividly as possible of the drawing, holding it "so that Graf S. could have seen nothing of it, however he might have turned himself." Regarding 3, Dr. Notzing states: "Just as I am leaving the room to make the drawing, I think of a square but draw a triangle."

For the next four figures, Fräulein E., a patient of Dr. Schrenck-Notzing, "twenty-four years old, suffering from hysterical troubles," was the percipient, Dr. Schrenck-Notzing the agent. General conditions of drawing similar to those in the previous experiments. In giving reproduction 6 to the agent, the percipient remarked: "I see a cross which persists, and is sometimes surrounded by a square, sometimes by a circle, some-

times by a border or frame. The frames wavered, but the cross remained." In experiments 8 and 9 the percipient was told that the first reproduction was wrong.

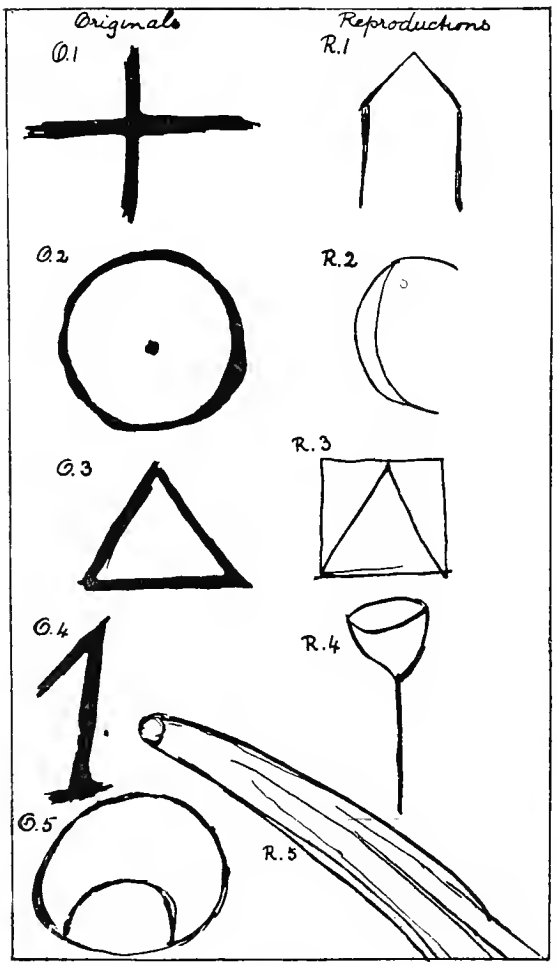

FIG. 615.

In figures 10 and 11 Fräulein A. ("a patient of a rather hysterical temperament") was the percipient, Dr. Schrenck-Notzing the agent. In these and the later experiments, the percipient sat on a chair with her back to the door, the agent sat in a chair opposite the percipient, "holding the paper on a book, the book held perpendicularly to the floor, with its back toward the percipient and the paper toward the agent." Is it perhaps hypercritical here to suggest that the author makes no reference to the possibility of indications by corneal images? In experiment 12 the agent "drew a 3 on a sheet of paper *under* the table, which was covered with a large cloth," this being "the only experiment where the drawing was made in the same room." For figures 12 to 15 Frau Eug., a Pole, aged twenty-seven, was percipient. Percipient was informed that 13 was "not a number." "The percipient now draws reproduction 13 (*a*). I look at her hand, and when she has done, say, 'Right, but it is not finished; draw larger.' The percipient draws 13 (*b*). I say nothing, but picture the original very clearly and vividly to myself. The percipient now draws reproduction 13 (*c*)."

After making reproductions (*a*), (*b*), (*c*), (*d*) for figure 14, the percipient asks: "Is it not a number, a zigzag, a letter?" Dr. Schrenck-Notzing says: "It is possible that as this went on I made some negative gesture. Suddenly she says, 'It is a square.' I say, 'Right.' She now draws unexpectedly under my eyes 14 (*e*), which completely reproduces the original. She might have guessed the square. But it is certain that there was absolutely nothing to suggest that the figure was to be completed by four small squares at the corners."

In making the reproduction of 15, the percipient remarked: "It is like a tower, square at the bottom—a ball. . . . It is like a pedestal." For the next three trials Fräulein A. was again percipient, but during each experiment "*agent and percipient are in different rooms, separated by a closed door.*" *O.* 16 represents "the staff of Æsculapius with the serpent." Dr. Schrenck-Notzing thinks that there is no object in the study "which could have led up to the idea," and that "corresponding association of ideas is excluded." As described by Dr. Schrenck-Notzing, with diagrams of the rooms, it seems exceedingly improbable that Fräulein A. could have obtained a glimpse of the drawings through, say, the keyhole of the door; but it is unfortunate that Dr. Schrenck-Notzing has not referred specifically to the possibility or impossibility of this, in connection with these three experiments. About figure 18, Dr. Schrenck-Notzing writes: "I began with the triangle, and then drew the

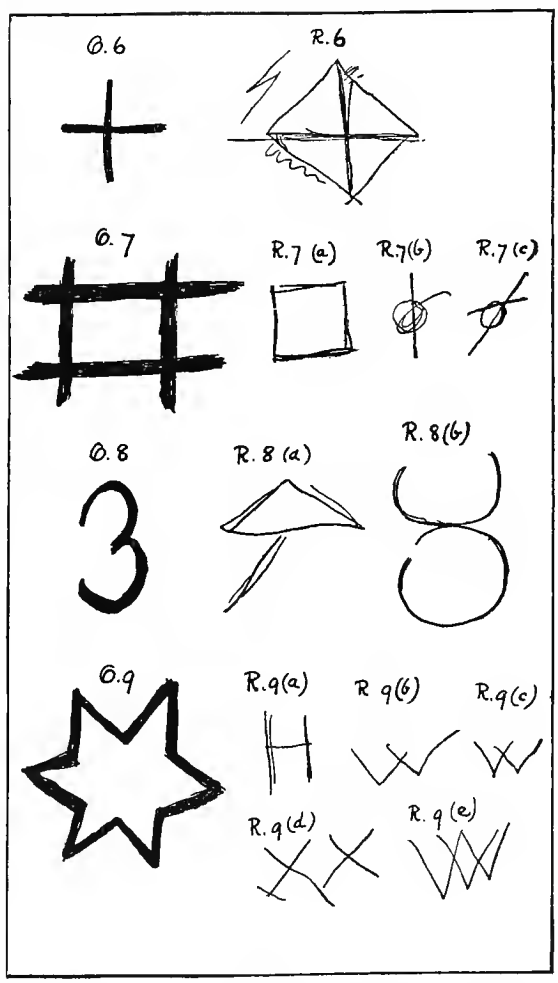

FIG. 616.

perpendicular as the base. The idea that thereupon occurred to me, that the figure was too simple, induced me to add a circle and to prolong the perpendicular to the circumference; finally I added the horizontal diameter."

For figure 19, the reproductions 19 (*a*) and (*b*) were

drawn with the same agent and percipient in different rooms, with the door closed. Agent says "Wrong,"—and continues experiment in same room with percipient under conditions similar to those of the carlier experiments. The percipient afterward makes reproductions 19 (*c*) and 19 (*d*). The author lays special stress on those four experiments 16–19, which "were done one after another in half an hour, with the same percipient and almost the same conditions throughout."

For figure 20 Graf S. was percipient, and 20 (*a*) was drawn with the agent in the other room. He is told that it is "wrong," and the trial is continued with the agent standing behind the percipient and looking at him while he draws (*b*)—(*e*).

In experiment 21 the percipient was Fräulein A., who gets no impression while the agent is in the other room. "I re-enter the study, and make the task easier for the percipient by saying 'Letters,' upon which she writes 'A, H,' I standing behind the chair. She then says, 'They are entwined,' and makes reproduction 21 (*b*), then 21 (*c*), which approaches the original still more. This experiment is a half success, but with a probability of guessing right by chance alone of one in twenty-four;

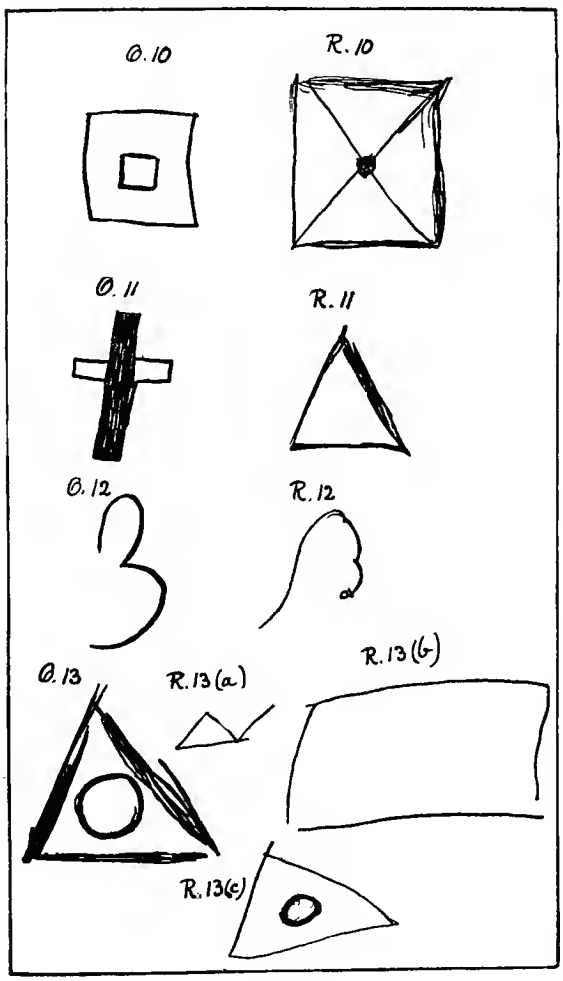

Fig. 617.

and subject to the need of making due allowance for the natural association of ideas, since the percipient would be likely to think first of the initial of her own name. As a failure, this experiment is interesting and instructive; regarded as a success, it would not prove thought-transference."

For the last trial Fräulein K. was percipient. 22 (*a*) was drawn while the agent was in the other room. "On

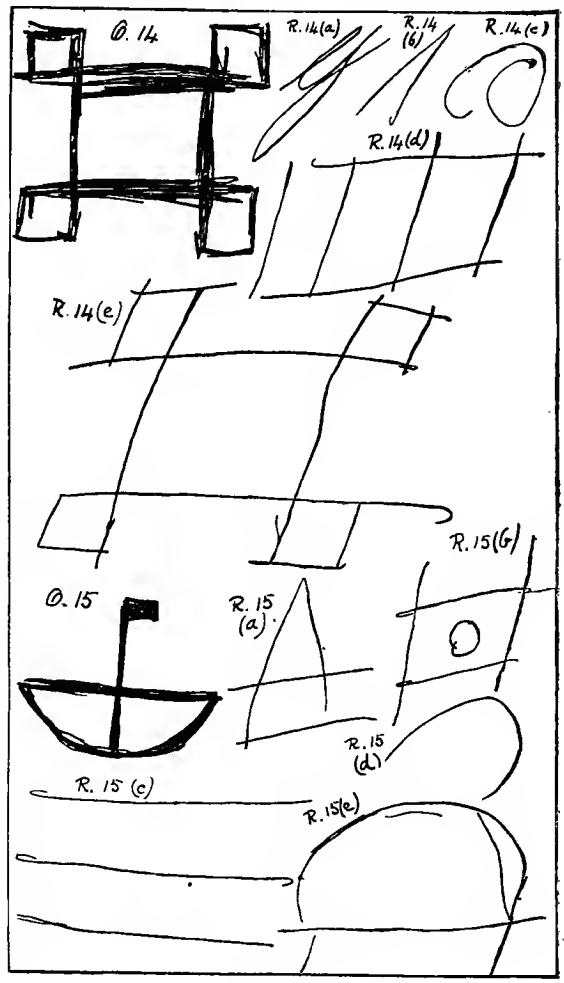

Fig. 618.

my return I look at the drawing—and say 'wrong,' and go on thinking intently of the original. She then draws reproduction 22 (*b*), I standing behind her chair and looking at her paper. I say 'Wrong, try again.' The percipient now draws a circle. I say 'Right, but not finished.' She now draws reproduction 22 (*c*), I keeping perfectly still, and giving her no further hint whatever." The author seems on the whole to be a careful experimenter and fully alive to the ordinary sources of error. The above experiments were made on various dates during 1890, and the author suggests that "it is advisable to experiment often, and little at a time." His general conclusions from his experiments, including the guessing of objects, persons, etc., as well as drawings, is that "after full allowance for possible sources of error, there remains, in the way in which the results were obtained, and in the amount of coincidence, something inexplicable which calls for further investigation, and seems to indicate with some certainty the operation of a factor not yet perceptible to our senses."

Professor Oliver J. Lodge gives an account (Part XX., Proc. S. P. R.) of some experiments (chiefly cards and diagrams) made with "two adult daughters" of Herr von Lyro, at Pörtschach am See, Carinthia. The sisters were

successful taking one as agent and the other as percipient alternately, but were not successful without contact or with other persons as agents. After describing "how clearly the effect seemed to depend on contact, and how abruptly it ceased when contact was broken," Professor Lodge says: "It is perfectly obvious how strongly this dependence on contact suggests the idea of a code, and I have to admit at once that this flaw prevents this series of observations from having any value as a test case, or as establishing *de novo* the existence of the genuine power." And although Professor Lodge was satisfied himself that no code was used, he states that none of the evidence which he can "offer against a prearranged code is scientifically and impersonally conclusive, nor could it be accepted as of sufficient weight by a sceptic on the whole subject." We need not therefore enter into any details here concerning this series.

Further experiments along the same lines as those made by Professor and Mrs. Sidgwick and Mr. Smith (*vide supra*) are recorded in Part XXIII., "Proc. S. P. R." by Mrs. Sidgwick and Miss Alice Johnson. Their object "was in the first place to obtain more complete evidence of thought-transference with agent and percipient in different rooms, and, if possible, at greater distances. We also varied the experiments, partly with a view to

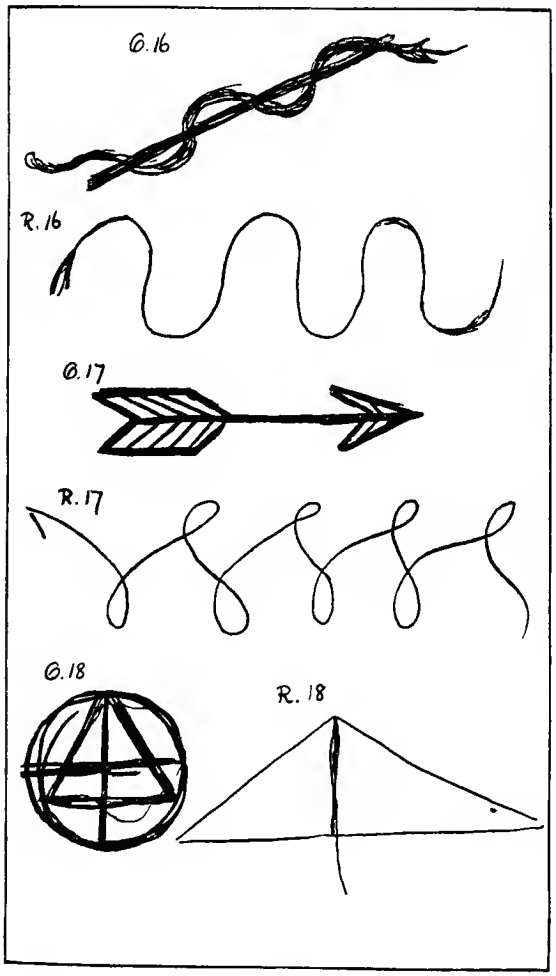

FIG. 619.

obtaining additional proof that no physical indications reached the percipient consciously or unconsciously, and partly in the hope of learning something about the conditions necessary to success. With these objects, we made experiments in the transference of ideas other than numbers, and sometimes employed automatic writing, table-tilting, and hallucinations as a means of getting at the percipient's impressions. In addition we

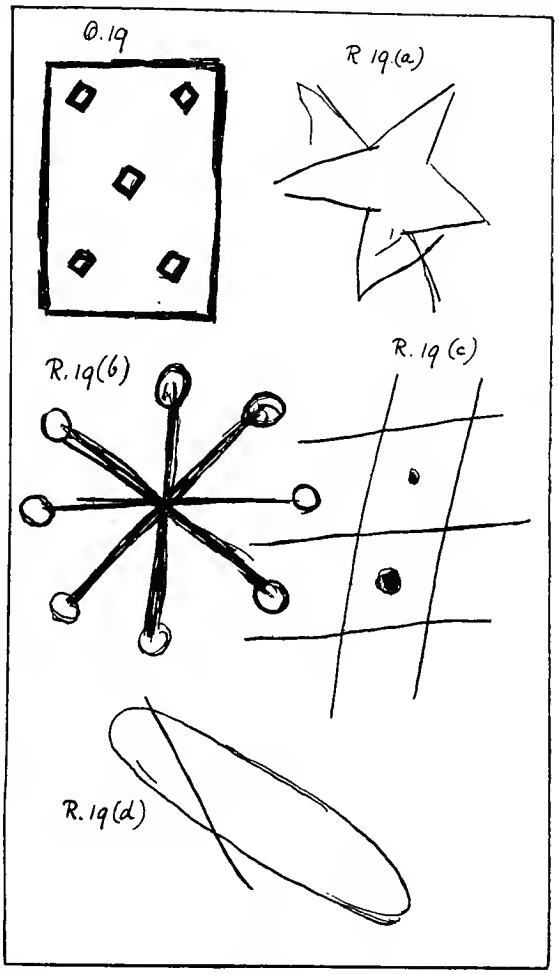

FIG. 620.

carried out a series of experiments in producing local anæsthesia and rigidity by, as we believe, mental suggestion."

It would occupy too much space here to describe even the conditions of these experiments in detail; as regards the numbers it must suffice to quote the general description of a few of the first experiments made with the agent on a ground floor and the percipient upstairs, the two rooms being, however, connected by a staircase "closed at the bottom by a door."

"The first experiments of this series with Miss B. were made on January 6, 1890. The persons present were Miss B., Professor Barrett, Mr. Smith, Mrs. Sidgwick, Miss Johnson, and T.; but T., with whom we had been experimenting, was hypnotized and not attending to what was going on. Mr. Smith hypnotized Miss B. and tried three numbers while in the room with her and speaking to her. There was some success with these, and then Mr. Smith and Miss Johnson went downstairs to the lobby. Miss Johnson drew a number at random out of a bag containing all the numbers from 10 to 90, and handed it to Mr. Smith, who then tried to communicate it mentally to Miss B. A little bell or gong was rung upstairs by Mrs. Sidgwick as soon as a guess had been made, and again when the party upstairs were ready to

begin another. As the bell was rung, Mrs. Sidgwick, who had previously been put *en rapport* with Miss B., said: 'There's another, Miss B.,' or words to that effect; and Miss B. began to look out for an impression, which usually came to her in a visual form. Mrs. Sidgwick noted down her guesses and remarks, while Miss Johnson noted the numbers that she drew from the bag, and at intervals we compared notes.

"Eight guesses were made in this way. The first two were failures, but in the remaining six the first digit was right in each case. Moreover, in two out of the six, Miss B. first gave the completely right number, but then changed her mind as to the second digit. Thus, the

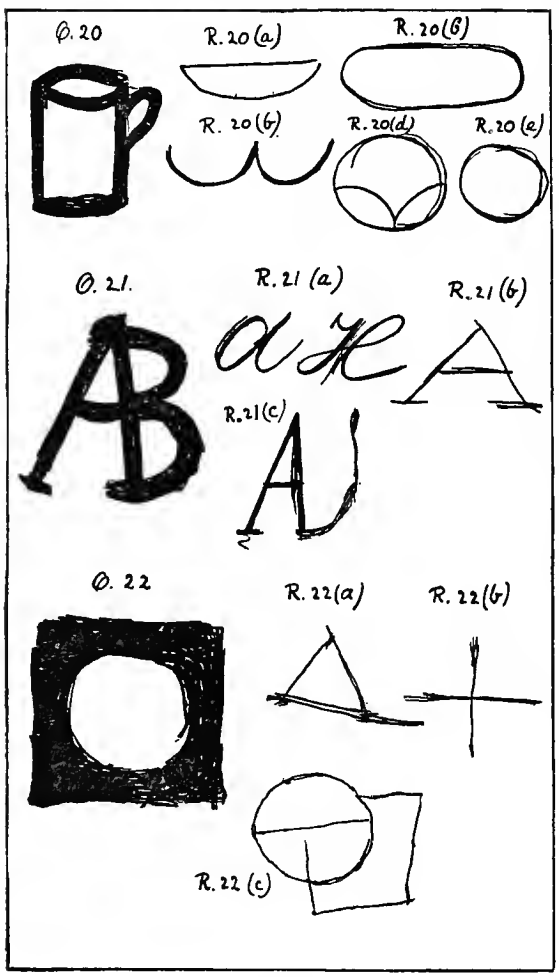

FIG. 621.

number being 21, she said: 'It's never another 2, is it? 2 and a 1? 8—28.' And again, with the last of the six, which was 41, she said: '4—better not go on doing any more, or I shall never be right, I'm sure. 4—1? Looks like a 1 : 46.' This occurred on other occasions also.

"It is hardly necessary to say that, as Mrs. Sidgwick was herself wholly ignorant of the number, it was impossible for her remarks to give any indications to Miss B."

The summary of the three first series of experiments—(1) Percipient upstairs, agent downstairs; (2) percipient downstairs, agent upstairs; (3) percipient in room and agent (12 to 17 feet distant) in passage, with closed door between—is given as follows:

NUMBER OF TRIALS AND DEGREE OF SUCCESS.

Quite right.	Digits reversed.	First Digit only right.	Second Digit only right.	Wrong.	Totals.
27	8	85	23	109	252

There were thus 27 complete successes in 252 trials, whereas chance alone would give only between 3 and 4.

A few words need perhaps to be said about the experiments in the production of local anæsthesia and rigidity by mental suggestion. These experiments, as the authors point out, are an extension of some experiments made originally by the late Edmund Gurney, who did so much valuable original work in connection with the hypnotic trance. The general method of experimenting was as follows:

"The subject, who was always in a normal condition at the time of the experiments, sat with his hands passed through holes in a screen which extended sufficiently above and on each side of him to prevent his seeing the operator or his own hands. The hands were spread out on a table and the finger to be operated on was silently indicated to Mr. Smith behind the screen by one of ourselves, either by signs or in writing. Mr. Smith generally said nothing while an experiment was going on, and he remained behind the screen until the testing was finished. The subject was frequently engaged by one of us in conversation on topics outside the matter in hand during the process of making the finger insensitive, but sometimes we encouraged him to attend to his own sensations, with results which will be described below."

It does not appear that the finger to be operated upon was chosen at random.

The methods of testing for anæsthesia were "touching all the fingers at various points in varying order, many times in succession, the subject being asked to say whenever he felt the touches," and the application of a current from a small induction coil through two wire terminals. The following is a summary of these experiments:

	Number of			
	Successes.	Partial Successes.	Failures.	Trials.
(*a*) With Mr. Smith pointing at the selected finger	19		6	25
(*b*) A glass screen placed over P.'s hands, Mr. Smith pointing at the finger	18		3	21
(*c*) Mr. Smith not pointing at the finger, in the same room with P., from 2½ to about 12 feet off	19	2	16	37
(*d*) Mr. Smith in another room across a passage, both intervening doors open, looking through an opera-glass at the finger	8		3	6
(*e*) Mr. Smith in a different room from P., an intervening door closed		2	12	14
(*f*) Mr. Smith pointing, but willing that no effect should be produced	4			4
Totals	63	4	40	107

The student must, however, be referred to the original record to obtain an adequate idea of the precautions taken by the authors to avoid not only ordinary, but extraordinary, sources of error. Taking the whole article, it seems to be the most valuable contribution to the evidence for experimental thought-transference that has yet appeared.

In considering generally the evidence for Thought-Transference, it is obvious that different students will doubtless form different opinions from the same records, and this is especially the case, perhaps, as regards experiments with diagrams or in the descriptions of objects, where no precise estimate of the probabilities can be made. It should, therefore, be continually borne in mind

that the value of the evidence does not depend exclusively upon several prolonged series of experiments with a few special subjects. In some cases, indeed, a greater value attaches to a shortly summarized and at first sight insignificant series, and this value attaches, on the one hand because the persons concerned are themselves investigators whose good faith is unimpeachable, and on the other hand because an accurate calculation can be made of the chances. A particularly good instance is that of the Misses Wingfield ("Phantasms of the Living," vol. i., p. 34), where the object to be guessed was a number of two digits (one of the numbers from 10 to 99) chosen at random. Out of 2,624 trials, there were 275 complete successes, whereas chance gives but 29. "In the last 506 trials, the agent (who sat some six feet behind the percipient) drew the numbers at random out of a bowl; the odds against the accidental occurrence of the degree of success—21 right guesses—obtained in this batch are over 2,000,000 to 1." A later series of 400 trials by the same ladies is described as follows ("Phantasms of the Living," vol. ii., pp. 653–4):

"The ninety numbers which contain two digits were inscribed on ninety slips of paper, and placed in a bowl. Miss M. Wingfield, sitting six feet behind the percipient, drew a slip at random, and fixed her attention on the number which it bore; Miss K. Wingfield made a guess at the number, and the real number and the guess were at once recorded in the table. The slip of paper was then replaced, the contents of the bowl shuffled, and another draw made at hap-hazard. The most probable number of right guesses for accident to bring about in the 400 trials was 4. The actual number of completely right guesses, was 27; in 21 other cases the two right digits were given in reverse order; and in 162 others, one of the digits was given rightly in its right place. The probability which this result affords for a cause other than chance is represented by 47 nines and a five following a decimal point; *i.e.*, the odds are nearly two hundred thousand million trillions of trillions to one!"

It does not, of course, immediately follow that Thought-Transference is the solution of the successes. It may be urged, for example, that the agent may have unconsciously sounded the numbers, and the percipient unconsciously interpreted the sounds. Such an explanation may appear the most probable to any person approaching the subject as a complete sceptic. It would, however, by no means account for the successes in all the shorter records scattered throughout even the Journal of the S. P. R., issued for private circulation among members and associates only, to which references may be given for the sake of the student: Journal S. P. R., vol. i., p. 318; vol. ii., p. 183; vol. iii., pp. 147, 179–191; vol. iv. pp. 33–37; vol. v., pp. 21–30, 111–126, 182–191, 276–279.

In some of the experiments recorded in volume v. the agent and percipient were in different houses, at a distance of 400 yards apart.

The most recent additional evidence that has come before us in favor of Thought-Transference, consists in a series of experiments conducted by A. Blair Thaw, M.D., of New York. The experiments were made with relatives and friends, and all conscious fraud was completely excluded. The trials were chiefly with cards, numbers, colors, and miscellaneous objects. The following extracts, are taken from Part xxiii., Proceedings S. P. R. We quote here only the first series of experiments, which seems to have been rather the most successful. Dr. Thaw writes: "It is manifest that in experiments intended to prove thought-transference all possibility of perception by the senses must be excluded. With this object the following rules were adopted in the experiments about to be described, and any infringement of them is noted in its proper place.

1st, with regard to the Muscular sense: there must be no contact between the person who is to take the active part and the person who is to try to receive the impressions.

2d, as to the sense of Sight: the percipient must have his eyes carefully covered with a dark bandage, and the object must be outside his field of vision, supposing no bandage were used.

3d, as to Hearing: The agent or agents must maintain perfect silence, speaking only when it is necessary, for the purpose of the experiments, as for instance, to tell the percipient what kind of objects he is to look for, as colors, numbers, etc. All cards, numbers, and colors should be chosen at random. . . .

The first series of experiments was made with the percipient in a light trance. The objects looked at by the agent being of a miscellaneous character, and taken from different parts of the house without the percipient's knowledge. The house happened to be rented, furnished, of friends, who left their bric-à-brac, etc.

The report, made verbatim, at the time of the experiments, is as follows:

First Series.

"New York, April 3, 1892.

"Mrs. Thaw, Percipient. Dr. Thaw, Agent. Witness, Mrs. Dow.

"Aftereach experiment, the agent touched the percipient's forehead to help her into the passive state, but never selected an object for the next experiment until after the contact was discontinued.

"Agent holds first two objects against white paper.

"1ST OBJECT. *Bronze Statuette, Classic Bust, Helmet and Beard.*—Percipient in one or two minutes says: '*Is it a picture?*' At this point, referring to percipient's putting it in form of a question, witness says impulsively, 'That's not quite right.' But this remark would hardly suggest what follows. After long pause, percipient continues: '*A reproduction of the human face. Dark. A statuette. Bronze. Beard. Hat on it. Slouch hat, cap. Has a ruff.*' (Back of bust suggests a ruff.) (Experiment took ten minutes.)

"2D OBJECT. *A Pair of Scissors.*—Agent writes above report on paper in his hand. Percipient says: '*Something white.*' Agent says 'No.' '*Writing on it.*' Agent puts away paper here, as it was evidently in percipient's mind. Percipient continues: '*If not white, shiny. A white shine, not a gold shine. Roundish. Engraved. A pair of scissors.*' (Percipient says something long and sharp was in her mind from the beginning.) (Experiment lasted four minutes.)

"3D OBJECT. *A Cabinet Photo of 'X.,'* brought by agent from upstairs before sitting.—Percipient says: '*Something square. A picture. A picture of a brass bed.*' Agent says 'Wrong.' '*Photograph of X.*' (Experiment took two or three minutes.)

"4TH OBJECT. *An Old Soiled* $10.00 *Bill.*—Percipient says: '*Square.*' (Percipient on being asked what she means by 'square,' says 'Square-cornered.' *It is a book with corners. Dark in color. Made of two colors. It is a kindergarten mat made by a child.*' Agent says, 'Wrong.' '*It is another picture. Has letters on it. A picture not of something human, but of something in nature. Has a big G on it, or like an O or two O's together. It is a picture in color. The color darker than the thing. The color like ink.*' (Experiment took ten to fifteen minutes.)

"5TH OBJECT. *A Red-covered Book*, with Black Cross and Letters on cover, 'Saint Paul,' by F. W. H. Myers. Percipient says: '*I think this is something dark in color. Is it anything square? Square and dark. It is a paper-covered book.*' Agent says, 'No.' Percipient continues: '*This time it is a book. It has writing on the outside. Reddish, brownish color. Capital E on outside. Is it the book on evolution?*' 'Wrong.' '*Is there anything stuck on it?*' 'No.' (Experiment took from five to ten minutes.)

"Percipient was told the name of the book and insisted that the name of Mr. Myers was in her mind all the time, but connected with the paper-covered Proceedings of the S. P. R., and when told the book was not paper-covered, gave up the name of Mr. Myers.

"6TH OBJECT. *Agent's Watch* (with Chain).—Percipient says: '*Bright. White Bright. No, gold bright. Either a watch or chain.*' (Experiment took two minutes.)

"7TH OBJECT. *Spectacle Case.*—A shining black with letters and arabesques and an eagle in gold on it. Percipient says: '*It's square; has corners. There's writ-*

ing on it. If not writing, has a picture on it. I think it's a book or a picture on a paper. I see it reddish. Long rather than square. Like a pencil or paper cutter, or knife. It shines. White shine or silver shine.' Agent asked color of letter. *' Gold, with one or two arabesques.'* (Correct.)

"8TH OBJECT. *Long Round Brass Wire Helical Spring.* Larger at one end.—Percipient says: *' This is dark colored. No shine. Black or brown. It's hard. It shines, white shine, metal. A silver thing. It's long. It's roundish. Is it a spoon? Is it a knife? I wonder if it has any glass on it. I think it's part silver and part cut glass. Maybe it's a steel shine. Is it a hat pin?'* (The outline of the object very much resembles that of an ordinary straight hat-pin.)

"*April* 4, 1892.

"Mrs. Thaw, Percipient. Dr. Thaw, Agent. Mrs. Dow, Witness.

"9TH OBJECT. *Small China Cup,* flowers painted on it.—Percipient says: *' Round. Bright. Steel. Top of mucilage. Rather flat. Money. Has another part. Perhaps something of glass. Partly glass or crockery. Ink-bottle.'* ' Color?' *' Greenish.'*

"10TH OBJECT. *Tortoise-shell Napkin Ring,* with name in script on side.—Percipient says: *' Not bright. Not light color. Square. Writing on it.'* (This object was familiar to agent not so much as a ring as for the writing on it, and from that point of view it, of course, appears square.) *' A book. Dark with white rim.* (Rim reflecting light.) *Bottom has corners. Something breakable.'*

"11TH OBJECT. A *Small Brass Key.*—Percipient says: *' Small. Smaller than the other object. Shines. Shines white.'* (True in some lights. A light-colored brass.) *' Is it sharp? Roundness of some kind.'* Agent asks: ' What kind?' *' Roundness, flat. Roundness also of a long thing. It has a handle. It is silver. Is it a toilet article?'* ' Color?' *'It has a gold shine.'*

"12TH OBJECT. *A Small Ear Syringe. Round Bulb.*—Percipient: *' Dark. Brownish. Flat. Corners. Long. A book.'*

"13TH OBJECT. The last object of this series is a book of Mother Goose's Melodies, with a picture of Mother Goose playing piano on the cover. Percipient: *' No shine. Not dark. Not white.'* At this point, agent being a little tired, stopped actual visualization of the book as an object, leaned back in his chair, and for the first time noticing Mother Goose was playing with her claws on the piano, being amused by this, fell to thinking of the general intellectual conception of the book. Percipient suddenly says: *' It has something to do with the mind.'* Agent in surprise exclaims: ' With the mind?' in a tone which discouraged percipient at first. Percipient continues: *' It has to do with library rather than bedroom. It has to do with Art.'* Agent asks, ' What art?' (This is an error of an impulsive character such as sometimes is made.) *' It is one of my crayons. It has something to do with writing, composition. Music too. It has been in the library. Either with something done in Art or with somebody doing something in an Art.'* Agent looking at Mother Goose at this time. *' Either work done or person doing it. It has something to do with a book. It has something to do with a book with a picture in it. It has something to do with a book of pictures or of music. It is a book. It is the Mother Goose book.'*

"The Mother Goose book was in percipient's mind from the beginning, but she wanted to see if it would persist. It continued to appear at times. The image was so clear that percipient was afraid of its being a conscious thought or guess, and so put it off.

"Thus of thirteen objects six were correctly named, the fifth object being called a book correctly, though the particular book was not named. (Five of the eight objects on the first day were named correctly.) In five of the remaining seven objects, the answer indicated that the percipient was on the right track, and only two of the experiments can be regarded as complete failures."

The account thus far given we trust will enable the reader to form some estimate of the more recent results achieved in experimental thought-transference. The evidence, however, for the general theory of telepathy is not confined to such experiments as we have been considering. Hundreds of spontaneous experiences depending on first-hand testimony have been published in the records of the S. P. R., the best explanation of which appears to be that one mind can be impressed by another independently of the recognized channels of sense. These two groups of occurrences, spontaneous and experimental, cannot but be regarded as mutually confirmatory of the general theory to which the name of telepathy was given by the Literary Committee of the S. P. R., in 1882. This view was put by Mr. F. W. H. Myers, as follows, in the introduction to "Phantasms of the Living:"

"I. Experiment proves that telepathy, the supersensory transference of thoughts and feelings from one mind to another, is a fact in nature.

"II. Testimony proves that phantasms (impressions, voices, or figures) of persons undergoing some crisis, especially death, are perceived by their friends and relatives with a frequency which mere chance cannot explain.

"III. These phantasms, then, whatever else they may be, are instances of the supersensory action of one mind on another. The second thesis, therefore, confirms, and is confirmed by, the first. For if telepathy exists, we should anticipate that it would exhibit some *spontaneous* manifestations, on a scale more striking than our *experimental* ones. And, on the other hand, apparitions are rendered more credible and comprehensible by an analogy which for the first time links them with the results of actual experiment."

The quality of the evidence for the first of the above theses has already been illustrated in these pages. It would be impossible here to convey to the reader any adequate notion of the second thesis, for the details concerning which the reader is referred specially to "Phantasms of the Living," published in 1886, and the Proceedings and Journal of the S. P. R., issued since that time.

The answer to the question whether the remarkable authenticated coincidences between phantasmal experiences and events occurring at a distance may not be due to chance alone, depends on "the frequency of phantasms which *have* markedly coincided with real events, and the frequency of phantasms which have *not.*" For the purpose of ascertaining this the late Mr. Edmund Gurney conducted a Census of Hallucinations, the result of which appeared to show, on the basis of his statistics, that there was unquestionably some causal relation between the coincidental experiences. Mr. Gurney received some six thousand replies to his inquiry, and it might be alleged that this was an insufficient basis for his conclusion. A much larger census has since been made under the auspices of the International Congress of Experimental Psychology, which met at Paris in 1889. The final results of this census, which was instituted in several countries, have not yet been completed. The only definite statement on this particular point which has been announced, was made at the meeting of the Congress in London, in 1892, by Professor Henry Sidgwick, who conducted the inquiry in England. On the basis of seventeen thousand answers, Professor Sidgwick concluded that "the actual proportion of coincidental to non-coincidental cases, after all deduction for possible sources of error, was in fact such that the probability against the supposition of chance coincidence became enormous, on the assumption of ordinary accuracy on the part of informants." The details of Professor Sidgwick's inquiry will be published this year (1893) in the Proceedings S. P. R. *Richard Hodgson.*

THYMACETIN. A new analgesic, prepared and named by Hoffman, of Leipzig, and brought to the notice of the profession in 1892 at a meeting of the Berlin Association for Psychiatria and Nervous Diseases, by Professor F. Jolly. It is closely allied to phenacetin, bearing the same relation to thymol that the older drug

does to phenol. It occurs as a white crystalline powder, only slightly soluble in water. Professor Jolly described the results of a series of experiments upon animals, and its use in a number of cases of nervous and mental diseases. He did not find that it had any antipyretic action, but its analgesic and hypnotic properties were undoubted. He found it of most service in headaches and pain of a purely nervous character, but when there was any organic disease it failed to produce any beneficial effects. He considered its action equal to that of phenacetin. As an hypnotic it was administered to twenty-six patients: in sixteen, it quickly produced a refreshing sleep; in ten, it failed to relieve the insomnia. The dose ranged from 3¾ to 15 grains, the usual hypnotic dose being 7½ grains. No toxic action was noticed, but it produced an acceleratian of the pulse and a complaint in some cases of a fulness, beating, and noises in the head.

Dr. Marandon de Monteyel has given particular attention to the physiological action of this drug (*Bulletin Gèn. de Thérap.*, January, 1893) and has formulated the following conclusions:

1. Thymacetin does not seem to exercise any action on sleep, the intellect, the vaso-motor system, the genital organs, the secretions, or the intestines.
2. Without influencing any of the other reflexes, it produces in a few instances a marked double dilatation of the pupil, but without disturbances of vision, the symptoms appearing during the first hour, and lasting from thirty to forty minutes.
3. It sometimes produces immediately after its administration, but only for a short time, however, dizziness associated with a slight degree of intoxication.
4. In three-fourths of the cases thymacetin causes a slight headache, this lasting several hours, appearing usually at bed-time, and, rarely, next morning on awakening.
5. It always increases for about two hours muscular force, as measured by the dynamometer.
6. It increases the bodily temperature to about one degree, the elevation like the decline of the same occurring gradually, returning to the normal point in about two hours.
7. During a period of two hours it increases the number of inspirations without modifying their rhythm.
8. The drug also causes, during the same period of two hours, a rise in the arterial pressure and an increase in the number of pulsations, but without producing cardiac palpitations.
9. Thymacetin, in two-thirds of the cases, causes toward the afternoon great lassitude, which often persists till the following day, even after waking; but there are no concomitant physiological or psychological disturbances produced.
10. It, in all cases, modifies micturition in three ways: (*a*) it accelerates or delays the desire of urinating; (*b*) it causes a urethro-vesical spasm, a momentary retention and dysuria, but these disturbances soon disappear; (*c*) occasionally during the passage of urine a scalding sensation is felt, which also soon disappears; these occur singly or in combination.
11. Exceptionally, before micturition, thymacetin produces shooting urethral pains.
12. In two-thirds of the cases it causes a bitter taste, accompanied with a sore mouth and a coated tongue, but no special odor of the breath.
13. In most individuals it produces, during an hour or more, a burning gastric pain more often localized, but sometimes felt all over the body; rarely a scalding sensation is felt along the œsophagus.
14. It is capable of producing a marked thirst, anorexia, and also gastric disturbances, which disappear on the suspension of the drug.
15. In a general way the organs become rapidly accustomed to the action of thymacetin, especially the bladder and the urethra, the stomach, however, is the only organ to become more and more susceptible to the remedy.
16. All the preceding physiological actions are produced by small doses; still, the sensation of dizziness, the temperature, the digestion, and micturition are influenced in direct proportion to the amount of the drug ingested.
17. Of all nervous disorders, general paralysis is the least susceptible to the action of thymacetin; in such cases dilatation of the pupil, or dizziness, was never observed, and in them urethro-vesical spasm was less frequent and less marked than in cases of insanity; on the other hand, in paralytics the spasm occurred more frequently than in epileptics. *Beaumont Small.*

THYMUS GLAND, DEVELOPMENT OF. The first statements regarding the development of the thymus gland contradicted each other completely. Arnold [1] asserted that it arose in common with the thyroid from the entoderm of the pharynx, while Bischoff [2] in general denied this. Remak,[3] in his great work, confirmed Arnold, and added that this gland arises from one of the branchial clefts; but he was placed in doubt after Ecker had described the large gland in the neck of the chick as the thymus. From now on, the prevalent view continued to be that the thymus was mesodermal in origin.

We can well understand why these various views should be entertained when we consider that, for studies of this sort, the methods at that time were very crude; but in spite of all this we are under obligations to Remak for so much light regarding many problems in embryology, and it really seems a pity that his own view, which later on proved to be correct, should have been abandoned on account of his over-caution. By the more improved methods, both Kölliker [4] and His [5] observed that the thymus must be of epithelial origin, and therefore accepted the old view of Remak. It may be added that at this very same time two elaborate papers were published by Afanassiew [6] and Watney,[7] in which they attempted to demonstrate that the gland arises from the mesoderm. More accurate methods were now introduced, and it soon was demonstrated by Stieda [8] that in many animals the thymus arises from the third branchial pocket. This was also confirmed by Born [9] (and many others, [10], [19]), who in this study introduced his celebrated method of reconstruction.

In the third part of his "Anatomie Menschl. Embryonen," His [5] brought forth the view that the thymus arises from the sinus præcervicalis, and is therefore purely ectodermal in origin. This view he attempted to strengthen in a later publication,[20] and it was quite generally accepted. Later, however, in a response to a paper by the author,[14] His [21] retracts his older view and admits that the bulk of the thymus has its origin from the entodermal lining of the third branchial cleft. He therefore considers the origin of the thymus still an open question, and until more careful researches are made, accepts the view of Fischelis [22] and of Kastschenko,[23], [24] that is, that it arises from both ectoderm and entoderm.

Shortly after the branchial arches are formed there appears at the dorsal side of each cleft a thickening of the entodermal cells, which soon separate from the entoderm to form distinct groups of glands. This is the condition of things in low vertebrates, and as the scale is ascended certain groups become more and more prominent, until man is reached, when only the two groups from the third branchial pocket remain to form the thymus.

In the fishes the general relation of these glands to the branchial clefts is shown in Fig. 622. These individual glands are soon united into one large gland on either side of the pharynx; in the bony fishes these groups unite into one gland before they have separated from the pharynx. In the reptiles the number of glands are reduced (Fig. 623) to correspond with this number of branchial clefts. Van Bemmelen discovered in the elasmobranchs that the posterior cleft, or rudimentary cleft, produced a distinct body which did not unite with the thymus. This he has termed the supra-pericardial body, and later its homology was found in many classes of vertebrates. In many reptiles it is unilateral, as shown in the figure. Considering their origin, they seem to be intimately related with the thymus, but in mammals it is

probable that they are added to the thyroid, and will be discussed under that heading.

In birds the third branchial pocket gives the main origin of the thymus, as shown in Fig. 624. Here we have a sharper line of demarcation between ectoderm and entoderm, as the branchial clefts do not break through neck; while this is taking place a pit is first formed, the sinus præcervicalis of His.

From the dorsal side of the first groove an invagination unites with the ganglia of the fifth nerve; from the second, the invagination is to the ninth nerve; and from the third and fourth it is to the tenth nerve. A section

as in fishes. We can now state with great certainty from what embryonic layer this gland arises, provided we have good serial sections to study. Very recently Kastschenko discovered a small gland in connection with the second branchial pocket, but as yet its fate has not been determined. It is no doubt a remnant of the portion of the thymus which arises from the same place in lower vertebrates. The third branchial pocket, however, becomes very prominent, grows toward the head, and is at no time blended with the ectoderm (Fig. 625). To be sure, it comes in apposition with the ectodermal invaginations of the clefts, but recent work has shown that these have to do with the ganglia of the cranial nerves, and do not unite with the thymus as thought by His and others. Moreover, it is by no means probable that these sense-organs of Froriep and Beard should suddenly leave the nerve-ganglia in certain regions and unite with glands. Both observations and principles of development contradict this. The fourth branchial pocket, as well as a rudimentary fifth (fossa subbranchialis), gives rise to a few small bodies, the nature of which is not as yet truly known. That, from the rudimentary fifth, no doubt, gives the gland which is homologous with Van Bemmelen's supra-pericardial body.

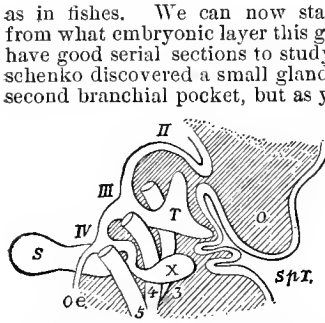

FIG. 625.—Dorsal View of a Reconstruction of a Chick 110 hours old. × thirty-five times. *II*, *III*, and *IV*, branchial pockets: *O*, operculum; *S*, thyroid; *spr*, sinus præcervicalis; *T*, thymus; *X*, body derived from the fourth branchial pocket; *oe*, œsophagus.

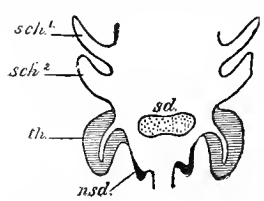

FIG. 626.—Diagram showing Branchial Pockets, and the Glands arising from them in the Human Embryo: *sch*,¹ *sch*,⁴ first and second branchial pockets: *th*, thymus: *sd*, thyroid; *nsd*, lateral thyroid.

In mammals the condition of things is much simpler (Fig. 626). The branchial grooves lie on the outside of the body, are shallow on their dorsal side and deep on their ventral. As these arches fall over one another, the grooves as well as the third and fourth arches are buried in the side of the

through these organs in the region of the vagus and of the thymus is shown in Fig. 627. The ectodermal invagination is absolutely blended with the vagus and is only in apposition with the thymus.

The pharynx-side of the branchial clefts presents about the same appearance as the external. The entodermal lining is in the form of slit-like pockets, which are better called branchial pockets, to differentiate them from the ectodermal side, or branchial grooves. As the head flexes upon the body the pharynx widens near the mouth and becomes narrower where the trachea is formed. There is a peculiar kinking of this region due to the rotation of the head. The first branchial pocket is converted

directly into the Eustachian tube; the second disappears completely; the third forms the thymus (Fig. 628); and the fourth becomes rudimentary and gives rise to the auxiliary thyroid glands.

The general appearance in the human embryo is quite similar to that in other mammals, as Fig. 629 shows. Already in this early stage of development, the third branchial pocket shows an ingrowth which indicates the origin of the thymus, The portion of the cleft represented by the fundus (F) is not continuous with the

thymus tube, and no doubt never plays any part in its formation.

The general view of the branchial pockets in a human embryo is shown in Fig. 630. The whole pharynx is represented as a cast and the branchial pockets are represented by the figures 1, 2, 3, and 4. It is the one marked 3 which is destined to become the thymus. It soon becomes separated from the pharynx and then grows into the thorax.

Before the thymus is separated from the pharynx it contains a distinct lumen. This is soon lost in birds, where the thymus grows toward the head. In mammals, where the thymus grows into the thorax, the upper part contains a lumen, while the lower part grows by a mass of sprouts (Fig. 631). This continues for quite a while until the whole organ is lobulated. New blood-vessels and lymph-cells grow through the epithelial gland and change its nature. The entodermal cells become packed together into the Horsal's concentric bodies as shown by Maurer for the fishes, and by Ecker[25] and by His[26] for mammals. These bodies correspond with the "pearls" in carcinomata, which are present in cancers, that arise from the whole epidermis, as well as those from the œsophagus. The Horsal's bodies do not therefore indicate that the thymus arises from the ectoderm.

During the first two years of life the organ continues to grow and the two halves gradually approach each other more and more, until they seem as a single body. It now lies immediately in front of the heart, and often sends two horns which extend on either side of the neck to the thyroid, as is the case in the birds. From now on, the organ gradually atrophies. *Franklin P. Mall.*

THYMUS GLAND: PATHOLOGY. In 1888 the practically discarded view that a form of asphyxia (asthma thymicum) dependent upon enlargement of the thymus, occurs in children, was revived by Grawitz. Since then a number of cases have been reported, having the clinical history of sudden death from suffocation, when the only abnormality discoverable *post mortem* was a marked enlargement of the thymus, usually associated with a more or less marked ecchymosis of its tissue. The difficulty in accounting satisfactorily for many cases of sudden death in children, and the frequency with which objective anatomical changes are absent, has perhaps

led to too much importance being attached to this lesion.

Clinically, the cases recorded have usually presented the symptoms of spasms of the glottis, with or without eclampsia. In half the cases the fatal attack was the first indication of illness; in the remainder, previous milder attacks of laryngismus had been noticed during the preceding week or fortnight. In a few cases these attacks had recurred with increasing severity.

In more than half the cases a moderate degree of rachitis is recorded. In about one-fourth no observation is recorded on this head. One-fourth are stated to be perfectly sound, and, especially, free from rachitis.

In a number of cases the fatal attack has immediately followed a bending backward of the head, as, for instance, when inserting a tongue spatula into the mouth (Pott).

The symptoms, as observed by Pott in four cases, were as follows: For several weeks attacks of laryngeal spasms had occurred several times daily. In the fatal seizure the children bent the head backward, with a noiseless gasping inspiration. The eyes were turned upward and the pupils dilated. The face, especially about the lips, became livid and swollen. The tongue, held between the teeth, became deeply cyanosed, and swelled to double its normal thickness, being pressed firmly upward against the hard palate. The veins of the neck were distended to the utmost and stood out like thick cords. The hands were clenched and the nails cyanotic. The legs were extended, the feet abducted and strongly extended. The vertebral column was curved backward. A few rapid twitches of the facial muscles followed, and afterward several gasping (*schnappend*) inspiratory movements without any audible inspiratory sound. Suddenly, the spasm relaxed, and the face became ashen-gray, with livid tongue and lips. Death ensued in one or two minutes from the onset of the attack. The heart's action ceased at the beginning of the seizure. Cervical reflex was lost immediately. No sounds of coughing or choking were heard. Artificial respiration, tracheotomy, and stimulation of the phrenic nerves produced no result. Urine and fæces were sometimes extruded on commencing the artificial respiration.

The post-mortem changes showed the heart distended, with dark cherry-red (?) blood. The vessels throughout the body moderately full. Lungs pale red, crepitant, sometimes with subpleural ecchymoses. In only a few of the cases, extensive areas of collapse, broncho-pneumonia, etc., were present, but these cases cannot be regarded as quite typical. Small emphysematous spots of distention beneath the pleura were commonly present. Larynx and trachea unaltered. Brain moderately full of blood, apparently normal. No alteration in phrenic or vagus nerves. The *thymus gland*, of a bluish-red color, often with ecchymoses. Size usually five to seven ctm. long, five to six ctm. wide, and two to three ctm. deep. Often extends over the right auricle, and in one case extended as far as the apex of the right ventricle. The lymphatics throughout the body were usually enlarged.

The explanations given as to the manner in which the thymus enlargement may be supposed to induce death vary with the different authors, and are in no case very convincing. It has been maintained that death is due to sudden pressure on the trachea, the space between the posterior surface of the sternum and the vertebræ being only about two ctm. in diameter in growing children. On the other hand, Scheele has shown that a considerable force (about 1,000 grammes) is necessary in order to compress the trachea; and the trachea never showed any post-mortem appearance of having been compressed. Another explanation given is that the pressure acts upon the right auricle or pulmonary artery. It is generally assumed that an acute venous congestion of the thymus is the main cause of the enlargement, and that the bending backward of the head, by disturbing the relations of the organs in the neck, tends to aid this. The original hyperplasia of the thymus is considered only to act as a predisposing cause.

It cannot be said that satisfactory mechanical grounds have been established for this cause of death. The clinical history seems to point to a disturbance of the venous system, possibly in the respiratory centres, rather than to mechanical suffocation. A. Paltauf denies the influence of the thymus hypertrophy, and considers the asphyxia as due to œdema of the bronchial mucosa.

The importance of the subject is due to the large number of otherwise unexplainable cases of sudden death from asphyxia in children, and in forensic cases the condition of the thymus should always receive attention.

THYROID EXTRACT. The treatment of myxœdema by the reintroduction, into the organism, of the gland itself, or fluids obtained from the gland, has been the natural outcome of the numerous experiments to determine the nature of that curious disease, and the relation between it and the thyroid gland. It was very clearly demonstrated that the absence of the thyroid, whether by disease or removal, resulted in all the phenomena characteristic of myxœdema, and further experimental work showed that, in animals, the grafting of a gland into the tissues prevented the onset of these symptoms, or if the degeneration had begun it was at once arrested and a normal state renewed. The first operation on the human subject was performed in Paris by M. Lannelongue, who reported the case to the Biological Society, March 7, 1890. The patient was a cretin, fourteen years of age, in whom the disease was well marked. About two-thirds of the thyroid of a young sheep was removed and immediately transplanted into the subcutaneous tissue below the right breast. The operation was done aseptically and the wound united without fever or suppuration. This was followed by numerous other cases, and the first successful performance in England is recorded by Dr. W. J. Collins, on May 2, 1892, at the Temperance Hospital, Hampstead Road. In all the cases reported the beneficial effects were remarkable. Within twelve hours some of the most distressing symptoms, such as menorrhagia, headache, and melancholia were relieved, and the improvement continued until, in some cases, the patients were apparently cured. The ultimate results, however, have not been recorded. The hope of the operators was to have the gland "vitalized" and restored to its functional powers in its new position. That this may occur is believed, as the beneficial effects were maintained for a prolonged period in many of the cases. Upon this the permanency of the cure depends, for if the graft is reabsorbed the condition of affairs that was present before the operation is likely to recur.

At the meeting of the British Medical Association in 1891, Mr. George Murray, of Newcastle-on-Tyne, proposed the subcutaneous injection of the fluid portion of the thyroid gland in the place of the transplanting of the gland, and reported his success in treating the disease by that method. He pointed out that the rapid effect produced by the older method must be due to the immediate absorption of the fluids in the fresh gland, and as for any permanent benefit, he did not consider that there was sufficient evidence to show that the gland ever became "vitalized." The good effects, he considered, were only temporary, and the operation would have to be repeated at frequent intervals. The advantages of the injections were very evident.

The following directions were given for preparing the extract: Cut the gland into transverse slices on a clean glass or earthenware plate, which has been rinsed in a five per cent. carbolic acid solution. All the utensils employed in the subsequent operations must be cleansed in the same fluid. Place the sliced glands in a mortar with some ordinary glass tubing; about two inches will be sufficient for a gland; and grind the whole up together until

the glands are thoroughly disintegrated. A fluid drachm of a mixture of equal parts of sterilized glycerine and a five per cent. solution of carbolic acid in water is then to be added, and when well triturated, transfer to a small stoppered vessel, and macerate for twenty-four hours. At the expiration of this period, squeeze out the fluid through a piece of muslin and filter through a double layer of sterilized paper under pressure. With a pressure equal to fifteen inches of mercury, a nearly clear filtrate of pale-yellow color is obtained, measuring about the same volume as the fluid added to the glands. If a pressure-filter cannot be used, it will be sufficient to pour off the supernatant fluid that separates during the twenty-four hours' maceration. In this case much less extract is obtained. Of the extract fifteen minims are employed for each injection, to be repeated every second or third day. The extract should not be used after four or five days, as it then causes some local disturbance. This method of administering the thyroid juice became general, and the same rapidly favorable results followed its employment.

The following year, Dr. H. W. G. Mackenzie reported a case in which he found the beneficial effects of the gland could be as satisfactorily obtained when administered by the mouth as by the other methods. At first he ordered his patient two fresh glands every day, but found that much less was sufficient; one gland twice a week, he stated, was quite sufficient, and, after the treatment has been continued for some time, a single gland once a week, or once a fortnight, would be all that was required to maintain its beneficial action. The gland may be given minced and mixed with a small quantity of brandy or beef-tea to overcome the nauseating taste, or the juice may be separated by allowing the minced gland to stand for half an hour with a few teaspoonfuls of water, and then straining through a piece of muslin. The extract may also be prepared by using glycerine, as in the method suggested by Dr. Murray for hypodermic use. The dose of the glycerine extract requires to be greater than when used hypodermically, twenty minims being given every day or every second day, until its influence is very decided. Priority in the internal use of the glands is claimed by Dr. Howitz, professor of clinical surgery at Copenhagen, who states that he used the glands in this way as early as March, 1892. He employed the glands of the calf, and gave them boiled, minced, and seasoned in various ways, together with the water in which they were boiled.

This internal use is followed by the same favorable results as when the extract is administered subcutaneously. In the cases reported an improvement was noticed during the first twenty-four hours, and before the third day the improvement in the symptoms and general condition was most decided. No ill effects were ever detected, except in a few instances when large quantities were given and continued for some days; in these cases an increase in the pulse-rate was noticed and the heart appeared to be enfeebled.

The internal administration is now very generally adopted, as the hypodermic medication is not without its unfavorable accompaniments. Very frequently pain and induration occur at the site of the injection, and occasionally an abscess supervenes. Great care also is required in preparing and preserving the extract, and there is always the risk of the fluid becoming impure and dangerous to use. The fresh gland is frequently employed, and it has been found that a moderate degree of heat does not lessen its virtues; but the extract prepared by macerating the gland in glycerine and water is the form in which it is preferred. A solid extract is now furnished, five grains of which represent the average dose of the gland. It is described as being prepared by extracting the secretion of the gland with glycerine and water, acidulating the liquid with phosphoric acid, and drying with sulphuric acid. Another dry extract is prepared by Dr. Howitz, by the addition of alcohol to the glycerine extract: this is given in doses of one-half to five grains.

The treatment of the disease really consists of two stages: the first, in which the disease is being overcome, and the second, in which the healthy state is being maintained. In the first period the quantity required is mentioned above, in the second the dose is not very definite. A single gland every week or every second week is thought to be sufficient, or if the extract is used, a dose of fifteen or twenty minims every second week is recommended. Dr. Murray estimates that the normal secretion is about one minim a day, and this should be supplied as nearly as possible.

It is early to estimate the value of this treatment, but it certainly gives relief and dissipates the disagreeable symptoms in a very short space of time. All observers are united in their praises of its effects, and no unfavorable reports have appeared to counteract its successes. Time and experience only can tell what the ultimate result will be.

Beaumont Small.

THYROID GLAND, DEVELOPMENT OF. Shortly after Rathke discovered the branchial arches in higher animals, Huschke[1] advanced the idea that the thyroid gland arises from the first arch. Later, however, he states that after the arches disappear the thyroid remains as their remnant.[2] A year later, Rathke[3] asserted that the thyroid arises as a bilateral organ from the posterior part of the trachea, immediately behind the larynx. This view was affirmed by Arnold.[4] Bischoff[5] accepted neither of these views, but added a third. According to him, the thyroid arises as a bilateral organ from the blood-vessels on either side of the neck.

The first careful investigations were made by Remak[6] upon the chick. In this subject, as well as in many others in embryology, he was the first to give accurate information. He found that the thyroid is entodermal in origin and arises from the ventral median line of the pharynx. At first it appears as a single vesicle, which soon divides into two parts, each half lying on either side of the trachea. Götte,[7] Müller,[8] and Seessel[9] confirmed Remak's views in general, differing only in minor points. They discussed whether or not the organ divided is a vesicle or is a solid body, although none of them found stages in which the thyroid was dividing. Remak placed the origin of the thyroid at seventy-nine hours in the chick; Müller in the third day; and Seessel very definitely in the second day before the head flexed upon the body.

His[10] revived the old view of Rathke by discovering that certain bodies arise from either side of the pharynx; he believed them to be the thyroid and the auxiliary thyroid of Remak. According to the illustrations which accompany his paper, the gland arises from the branchial cleft between the second and third aortic arches, therefore the second cleft. Later, however, he abandoned this view and accepted that of Seessel, who worked under his guidance. Later, Kölliker[11] accepted the old Remak-Seessel view for the rabbit, as His[12] did for man.

This group of excellent workers seemed to set the subject aside for a while, but, immediately following their work, two authors simultaneously described the thyroid as being bilateral in origin, arising from a branchial cleft on either side of the neck. Stieda[13] proved definitely that a glandular organ arises from the clefts on either side of the neck, but did not know from which cleft, although he was inclined to accept the fourth. Wölfler[14] did not employ very accurate methods, and therefore got the location of the origin of the gland in the first branchial cleft—the one which later forms the Eustachian tube. He was so enthusiastic over his discovery that he denied altogether a median thyroid, although he had never seen the thyroid in connection with any cleft. Discussions naturally bring forth more accurate investigations, and in this case they bore their fruits in Born's paper.[15] The paper of Born not only threw a great deal

of light upon the subject in question, but also added greatly to our methods of investigation. He introduced a method which to us now seems so logical that it is a surprise that it was not employed earlier. He began with embryos of the pig before the thyroid appeared, and followed them stage by stage until the organ was fully formed. In each stage the enlarged sections were drawn upon wax plates of the proper thickness, then cut out and the pieces piled upon one another, thus forming very accurate models of the various specimens studied. He then followed the lateral thyroids of Stieda and Wölfler, and found that later on they were added to the median thyroid of Remak. The great difficulty was therefore solved by this method. Instead of these various authors contradicting one another, they in reality described correctly only different portions of the same story. According to Born the lateral thyroids arise from the fourth branchial clefts. Since then, Born's view has been confirmed in a variety of mammalian embryos by different writers.[16–26]

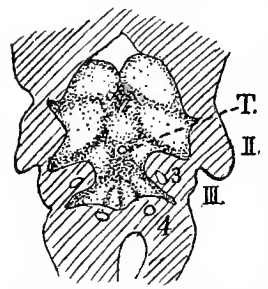

FIG. 632.—Reconstruction of the Mouth of a Chick Eighty-eight Hours Old. The floor of the mouth is exposed by cutting off the back of the head. Dorsal view. × 20 times. *T.*, tuberculum impar, back of which is the opening of the thyroid; *II*, *III*, branchial arches; 3, 4, third and fourth aortic arches.

The subject of the origin of the thyroid and thymus (see Thymus) has been greatly complicated by a group of glands which arise from the degenerating branchial clefts and form the so-called auxiliary thyroid glands. From a phylogenetic standpoint all glands which arise from the clefts must be viewed as thymus. The great bulk of thyroid arises from the ventral wall of the pharynx in the region of the second cleft. As the clefts gradually disappear in the evolution of the vertebrates, the glands from the hindermost clefts no longer unite with the main bulk of the thymus, and often remain as distinct glands—the supra-pericardial bodies of van Bemmelen, accessory thyroids of de Meuron, post-branchial body of Maurer, or as the corpus Y of the writer.[26] In the mammals the main bulk of the thymus arises from the third cleft, and the auxiliary thyroids seem to unite with the median thyroid as described by Born. In spite of the great amount of work which has been done upon this subject, it still seems to the writer that there is yet considerable darkness regarding it.

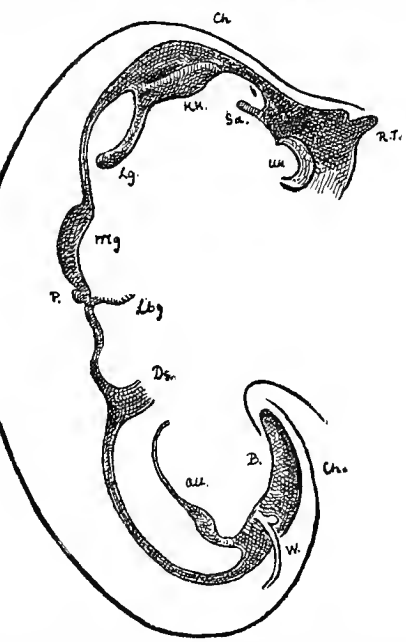

FIG. 633.—Abdominal Canal of a Human Embryo. × 20 times. (After His.) *Uk*, lower jaw; *Sd.*, thyroid; *Lg.*, lung; *Mg.*, stomach; *P.*, pancreas; *Lbg.*, bile-duct; *W.*, Wolffian duct.

The general view is that the thyroid has three distinct origins in nearly all vertebrates—a median and two lateral. The median arises from the ectoderm of the middle line in the neighborhood of the second branchial arch (Fig. 632), and the lateral from the most posterior branchial clefts; in mammals, the fourth.

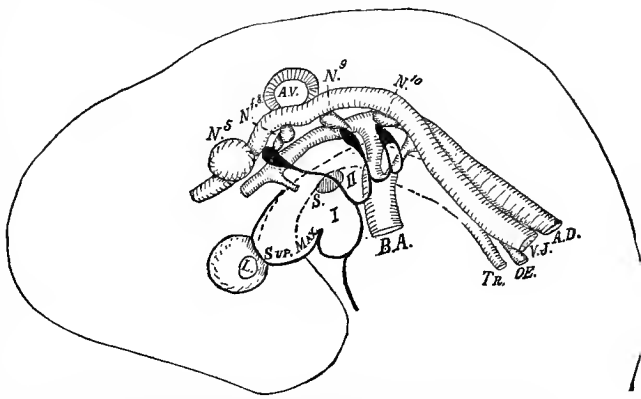

FIG. 634.—Profile Reconstruction of a Dog's Embryo, 6 mm. long. × 25 times. N^8, $N^{8'}$, N^9, N^{10}, ganglia of cranial nerves; *I*, *II*., branchial arches; *A. V.*, auditory vesicle; *Tr.*, trachea; *OE.*, œsophagus; *V.J.*, jugular vein; *A.D.*, descending aorta; *B.A.*, bulbus aortæ; *S.*, thyroid gland.

The median thyroid arises in all vertebrates from the entoderm of the pharynx shortly after the branchial arches are well formed (Fig. 632). This has been known since the time of W. Müller, and, although contradicted many a time, has of late been verified by so many careful observers that there is no longer any doubt whatever regarding it. In some mammals (the dog, for instance) it arises as a vesicle, which becomes solid before it separates from the pharynx, and when separated soon becomes lobulated. It now gradually shifts itself into the tissue of the neck, and in early stages lies in front of the aorta just as it leaves the heart (Fig. 634). The median gland now becomes constricted into two parts, one of which is situated on either side of the neck, but they remain connected by a band—the isthmus. Its origin in the human embryo is much the same (Figs. 635 and 636). According to His, it remains a vesicle for quite a long time, and the separation from the pharynx is quite late or may not take place at all. Later, however, the formation of the ligamentum hypothyroideum cuts the duct (*d. thyreoglossus*) into two, thus forming two ducts. The half communicating with the mouth has been termed by His *ductus lingualis*, and the one with the thyroid as the *ductus thyroideus*. His has found the ductus lingualis in five

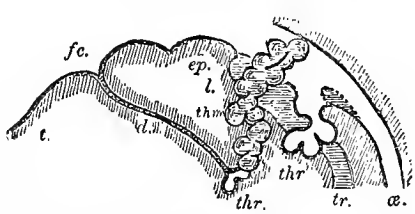

FIG. 635.—Pharynx, Thyroid, and Thymus of a Human Embryo. × 25 times. (From Quain after His.) *tr.*, Tongue; *fc.*, foramen cæcum: *ep.*, epiglottis; *thm.*, thymus; *thr.*, median thyroid; *thr'*, lateral thyroid; *d.*, ductus thyreo-glottus.

adults, and in all cases the ductus thyroideus was present also. The latter is always imbedded in a median lobe of the thyroid, and the former opens into the foramen cæcum of the tongue. The ductus thyreoglossus may be broken into a series of vesicles, as first described by Verneuil, but as a rule it disappears fully, its only remnant being the foramen cæcum.*

The lateral thyroids were first demonstrated by Stieda and by Born, although Rathke, His, and others had in

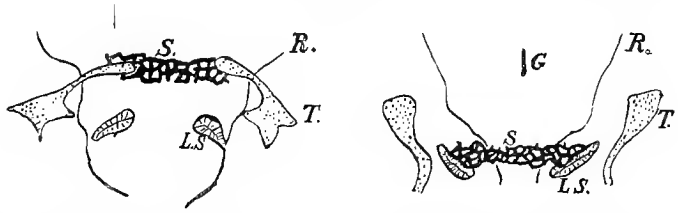
the neck, as in the auxiliary thyroid glands, which have perplexed so many investigators. According to Kastschenko the lateral thyroid of mammals plays a very minor part in the formation of the mature organ, while according to His it forms the major part. A true blending of the two does, however, take place, as shown by the investigations of Born and His. (Fig. 639.)

The further development of the thyroid is by means of sprouting, so that the enlarged organ is a plexiform mass of cylinders of epithelial cells. Blood-vessels grow in between them, and soon the cylinders show constrictions which cut them up again and again. They now become hollow, and at the same time there is a secretion of the colloid substance. The cut-up cylinders become more and more distended, and thus the adult thyroid is



FIGS. 637 and 638.—Diagrams of two stages of the development of the lateral thyroids. Slightly modified from Born. *R.*, border of the pharynx; *T.*, thymus; *G.*, glottis; *L.S.*, lateral thyroids.

all probability described them from time to time. The true meaning of them was fully made out by Born and by de Meuron, the former having discovered that they unite with the median thyroid in mammals, the latter having studied them from a comparative standpoint. Diagrams of the branchial pockets for some of the different classes of vertebrates are given in the article Thymus, and by them it is shown that a rudimentary branchial pocket exists in all of the classes. In certain reptiles there is but a single one on the left side, the one on the right not having developed. We can view this state of things only as an intermediate one between the reptiles (in which they develop on both sides) and the birds. In all classes the hindermost cleft gives rise to a distinct gland known as the supra-pericardial body of van Bemmelen and as the accessory thyroid of de Meuron.[28-30] In the selacians these bodies remain far away from the median thyroid, and they never unite with it. In higher animals they gradually approach the median thyroid nearer and nearer, and in mammals they unite completely with it. Fig. 636 shows the general relation of these glands in a human embryo before the lateral thyroid is fully separated from the pharynx. Figs. 637 and 638 show two stages in which the lateral thyroid is approaching and uniting with the median. This is brought about by a double shifting. The median thyroid sinks deeper and deeper into the tissue of the neck, and practically lies in contact with the lateral thyroids before they separate from the pharynx. When these in turn separate from the pharynx they are shoved into the tissue of the median thyroid instead of into the ordinary mesoderm tissue of the neck.

It will be noticed that the lateral thyroids do not always arise from the same branchial clefts: in selacians from the seventh; in reptiles from the fifth; in mammals from the fourth. It is only in mammals that they really unite with the median thyroid. Viewing the thing from the standpoint of homology, what is lateral thyroid in mammals is thymus in lower animals; in both selacians and reptiles the fourth cleft gives rise to a portion of the thymus. We must therefore view the lateral thyroid as a portion of the thymus which is now united with the thyroid. In lower animals the secondary union of the gland from degenerating clefts with the median thyroid does not take place, and they remain in the tissue of composed of a mass of hollow spheres covered with a layer of epithelial cells and filled with colloid substance. When half of the thyroid is removed by an operation or otherwise, the remaining portion soon loses its colloid and returns to its "embryonic state." It enlarges to its

former size and again forms the colloid spheres much after the fashion it did in the embryo.[31]

THYROID GLAND: PATHOLOGY. Goître.—In the past few years total extirpation of the gland has been practically abandoned, on account of the tendency to myxœdema observed after this treatment. Enucleation of the tumor or partial extirpation is not, as a rule, followed by myxœdema; and as the portions of thyroid tissue left tend to undergo a spontaneous atrophy, the objects of operative treatment are equally well attained by partial extirpation. Electrolysis has been also reported as successful in several cases.

Lustig has advanced the remarkable hypothesis that goître is caused by a specific bacillus present in certain drinking-waters. He claims to have produced it experimentally, in uninfected localities, in horses which were made to drink freely of certain water taken from the Aosta Valley, where cretinism and goître are endemic. He also claims to have isolated a specific water bacillus from these waters, not found elsewhere. In the absence of any experimental evidence from the employment of pure cultures, the conclusions of this author appear to be premature. Filtration and boiling of water are recommended by him as prophylactic measures.

A. Wölfler ("Zur Chirurgischen Anatomie und Pathologie des Kropfes und Nebenkropfes." Arch. der Chir., XL., 1890), in an extensive monograph on the subject of thyroid tumors, retains his classification of (a) Hypertrophy of the Thyroid (uniform enlargement); (b) Vascular Goître, of clinical significance only, without any definite histological relations to true hyperplasia of the thyroid; (c) Fœtal Adenoma; nodular insular overgrowths of imperfectly developed thyroid tissue, situated deep in the gland substance; (d) Adenoma gelatinosum —colloid goître. In the same article a large number of anomalous situations of the overgrowths are instanced (retro-sternal and intro-thoracic goître, etc.). Accessory thyroid tumors are regarded by Wölfler as sometimes arising from detached rudiments of the gland itself, at other times from the thyreo-lingual duct or accessory thyroid glands. The existence of these latter plays an important rôle in causing the goître to assume unusual forms, or to occur in unusual situations. Their origin appears to be either in the remnants of the lingual duct or in the aortic glands.

R. Paltant considers ("Ziegler's Beiträge zur Path. Anatomie," XI.) that the cylindromata occasionally found near the bifurcation of the carotid have nothing in common with accessory thyroid glands, but form a distinct group of tumors.

Intra-tracheal Struma.—R. Paltant, as the result of a careful study of the subject of growths of thyroid tissue occurring within the trachea, has come to the conclusion that the condition is not caused by the formation of isolated embryonic rudiments, which become accessory glands, but rather are simply offshoots of the main thyroid gland, and arise in extra-uterine life. The essential condition necessary appears to be a fusion of outlying portions of the thyroid with the cartilage of the trachea, or with the thyroid cartilage during fœtal life.

Myxœdema.—The Myxœdema Committee of the Clinical Society of London has published a special report upon this subject, in which 109 cases are tabulated, and which contains a number of interesting observations.

The following are the conclusions arrived at: (1) That myxœdema is a distinct disease which is (2) commonest in middle age, and affects women oftener than men, in the proportion of 6 to 1. That (3) the one condition common to all cases is a destructive change of the thyroid gland, of which (4) the most common form consists in the substitution of a delicate fibrillar tissue for the proper glandular structure of the thyroid. (5) That there is an interstitial development of fibrous tissue, which, while most frequent in the skin, is also met with in the viscera, and is suggestive of an irritative process. (6) That the anatomical observations, while showing cause for changes in the skin, hair, etc., and for the falling out of the teeth, in the alteration and gelatinous infiltration of the interstitial tissue, afford no explanation of the affections of speech, movement, sensation, consciousness, and intellect which form part of the disease. (7) That chemical examination of the comparatively few available cases fails to show the existence of an excess of mucin in the tissues, corresponding to the amount recorded in the first observations (Ord), but that this discrepancy may be in part due to the fact that liquefaction of the integuments, though generally characteristic of myxœdema, varies considerably throughout the disease and often disappears before death. (8) That in experiments made upon animals, especially on monkeys, symptoms resembling in a very close manner those of myxœdema have followed the removal of the thyroid gland, performed under antiseptic precautions and with, as far as could be ascertained, no injury to the adjacent nerves or the trachea. (9) That in such experimental cases a large excess of mucin has been found to be present in the skin, fibrous tissues, blood, and salivary glands: in particular the parotid gland, which normally contains no mucin, presented this substance in quantities corresponding to what would normally be found in the submaxillary gland. (10) That the full analysis of the results of removal of the thyroid gland in man, demonstrates, in a large proportion of the cases, that the subsequent development of symptoms corresponds exactly with those of myxœdema. (11) That in cases where the operation has been followed by no such symptoms, the immunity is probably due to the presence and subsequent development of accessory thyroid glands, or to the incomplete removal of the thyroid, or to insufficiently long observation of the patients, after operation. (12) That while injury to the trachea, atrophy of the trachea, injury to the recurrent laryngeal nerves, injury to the cervical sympathetic, and endemic influences, have been assumed to be the true cause of operative œdema, there is, in the first place, no evidence to show that, of the numerous and varied operations on the throat (neck), any have been followed by these symptoms, save when the thyroid gland has been removed; and that myxœdema has occurred in patients whose thyroid glands have been removed, but who never lived in localities subject to endemic cretinism. (13) That whereas, in spontaneous cretinism, women are more commonly affected than men, in the operative form no important numerical difference has been observed. (14) That myxœdema in adults is the same as sporadic cretinism in children; and that myxœdema is identical with cachexia strumipriva, a close affinity existing between the former and endemic cretinism. (15) That while these several conditions appear to depend upon loss of function or destruction of the thyroid gland, the ultimate cause of such loss or destruction is, at present, not evident.

Course of the Disease.—Improvement in about fifty per cent. Stationary in twenty-five per cent. Fatal in fifteen to twenty-five per cent., death being often due to some intercurrent disease. Of 12 deaths tabulated by the Clinical Society there were: Pneumonia, 3; bronchitis, 1; exhaustion, 2; coma, 2; collapse, 1; suffocation, 1; increasing slowness of mind, 1; emaciation, 1.

An analysis of the 109 cases gives the following results:

Symptoms.—Personal and family history: Tends to occur in connection with neurosis and phthisis; sometimes hereditary. No connection with syphilis. Most frequent in married women, in whom child-bearing has been excessive. Is no bar to pregnancy.

State of patients: Constant increase in bulk and weight. Swelling most conspicuous in face and head, but usually involves the whole body. Physiognomy is "cretinoid," "mask-like," "placid," or "heavy." Features puffy

and coarse. Eyelids swollen and transparent, eyebrows raised. Extremities swollen and clumsy-looking, usually cold. Nails stunted and brittle. Hair dry and brittle; tendency to baldness. *Thyroid* shows distinct tendency to diminution. Temperature subnormal; a rise to normal temperature in myxœdematous patients often indicating pyrexia. Watery dropsy sometimes present about ankles—always slight and transitory. *Sensation* retarded in about half the cases; abnormal tactile sensations common. Paresis common, especially about the neck. Severe paralysis only occurs through some complication. Incoördination common. Contractures rare. Reflexes usually normal: in a few cases delayed, occasionally exaggerated.

Intellectual changes: Slowness in thought and action almost invariably present. Writing good. Irritability usually marked, sometimes alternating with abnormal placidity. Sleep usually good, sometimes somnolence during daytime. Delusions and hallucinations in about half the cases, usually associated with insanity either as mania, melancholia, or dementia. Memory usually impaired. Speech deliberate, thick, or hesitating in nearly all cases. Eyes tend to water. Slight diminution in acuteness of vision. Exophthalmos observed once or twice in early stages. Hearing impaired in more than half the cases. Taste often impaired, smell sometimes so.

Circulatory system: Blood not altered. Heart usually normal. Arteries rarely atheromatous. Pulse weak, soft, and slow. Capillaries (!) nearly always dilated on face. Hæmorrhages from throat, gums, nose, uterus, etc., often occur in well-marked cases. Cutaneous ecchymosis rare.

Respiratory system does not present any changes typical of the disease, but intercurrent respiratory complications are often the cause of death.

Digestive system: Teeth tend to loosen and fall out, or to become carious. Gums often swollen, spongy, and bleeding. Tongue, uvula, and soft palate usually swollen. Bowels usually constipated.

Urine: Specific gravity lowered. Urea diminished. Albumin often present in later stages, absent in earlier. Sexual system not affected. Recovery noted in one instance only. Disease is extremely chronic and may last over ten years. Its general tendency is to shorten life.

Pathological changes based upon about twenty-five cases, in which autopsies were performed, the tissues and organs being examined microscopically in twenty cases.

Fat.—Subcutaneous fat abundant, and fat in other situations usually in excess. In one instance subcutaneous tissue found to be "gelatinous," and in another "œdematous." No unusual appearance noted in the remainder. Slight anasarca common.

Thyroid gland in every case reduced in size, color pale-yellow or buff-colored. Consistency tough, firm, and indurated. In some cases the affection more advanced in one lobe than in the other. In one case carcinoma of the gland was noted (Gulliver, "Trans. Path. Soc.," xxxvii., p. 511). Microscopically, nearly the whole of the gland converted into delicate fibrous tissue, here and there infiltrated with clumps of cells, replacing the gland vesicles. Adventitia of the arteries swollen and infiltrated with small round cells. In some cases, where parts of the gland still show the vesicular structure, the walls of these vesicles are seen to be infiltrated by a round-celled growth. In extreme cases the glandular structure may be altogether absent. Almost no colloid material recognizable, the sole remains of thyroid gland tissue being a very few epithelial corpuscles buried in the collections of leucocytes seen throughout the dense stroma.

Kidneys show in two-thirds of the cases more or less interstitial change. "In some not greater than might be anticipated in persons of adult or advanced life."

Heart.—Left ventricle hypertrophied in the cases in which the kidneys were granular. Arteries do not show degeneration to any unusual extent.

Skin.—Epithelium in the region of sweat-glands swollen, with nuclear proliferation, the lumen of the tubes becoming obliterated. In later stages a nucleated fibrous growth seen outside the tubes. Similar changes occur in the sebaceous glands, which become represented by irregular masses of nuclei which tend to undergo total or partial absorption. A nuclear proliferation is liable to develop around the hair-follicles. In one case thickening of the perineurium was observed in the nerve-filaments of the subcutaneous tissue. An appearance like œdema was noted in one instance only. In five cases fibrosis was present in the superior cervical ganglion, and in three others there was probably interstitial change.

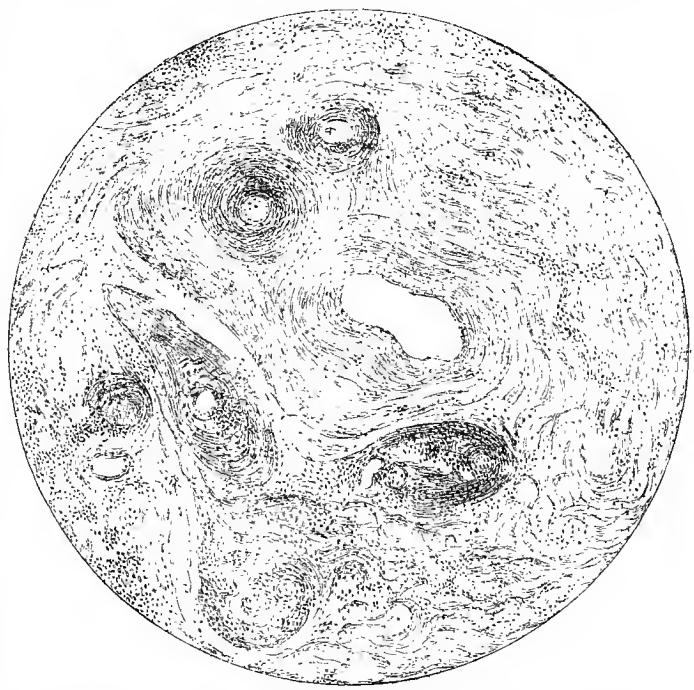

FIG. 640.—Section of Thyroid Gland, showing almost complete replacement of its vesicular structure by fibrous tissues. (Dr. Ord's case. Report on Myxœdema. Clinical Society's Transactions. 1888.)

Hun and Prudden (*American Journal of the Medical Sciences*, 1888) give a very accurate account of four cases, in two of which autopsies were obtained. The conditious described are the same as those met with in the cases collected by the committee of the Clinical Society. Chemical analysis of the skin showed no excess of mucin over the normal. Microscopically the skin showed a marked dilatation of the lymph-vessels in the zone between the corium and rete, and the interfibrillary spaces were widely open. The fat showed slight atrophic changes. Nervous tissues were unaltered. In all the cases faradic irritability was unaltered; reaction to galvanic current was diminished.

The authors have also tabulated the results of analysis of one hundred and fifty cases in their memoir, the statements made corresponding closely with those since given by the Clinical Society.

Some interesting chemical results are communicated by Halliburton as to the relative amounts of mucin found in normal and myxœdematous tissues. The methods employed were as follows:

The tissue was first finely minced and weighed, and then subjected to the action of methylated spirits for a

few days. The spirit was then poured off and either lime-water or baryta-water (diluted with five volumes of distilled water) added. After being allowed to stand in contact with the tissue for some days, the lime or baryta-water was filtered off and the mucin in it precipitated by a slight excess of acetic acid. This precipitate, granular at first, became flocculent after standing for a few hours; it was then collected in a filter, which had been dried at 100° C., and weighed; then it was washed with water, acidulated milk, acetic acid, distilled water, rectified spirit, and ether; then dried at 100° C. to constant weight, and weighed.

The following table shows the average results of these analyses of human tissues:

Tissue.	Percentage of mucin in Normal tissue.	Myxœdema.
Skin	0.374	0.385
Connective tissue	0.521	1.65
Spleen	none.	2.21
Lung	none.	0.72
Parotid	trace.	0.188
Fluids, blood, ascites, cerebro-spinal fluid, etc	.....	none.

In myxœdema, experimentally produced in animals, a much more uniform increase in the percentage of mucin was observed. The name myxœdema, as applied to the condition occurring in man, is not to be understood to signify the constant presence of mucinous infiltration. The fact that an enlargement of the pituitary body has been observed in animals after removal of the thyroid gland, has led to investigations as to the condition of that body in myxœdema; but no relation appears to exist in man which points to a pituitary enlargement, either after thyroidectomy or in cretinism. Langhans, after investigating the subject, came to the conclusion that any hyperplasia of the thyroid is connected with the original goître, and not caused by removal of the gland.

Treatment.—Up to 1890 no satisfactory specific means of treatment existed, and no general improvement could ever be attributed to the effects of treatment, though some of the symptoms appeared at times to be relieved. Warmth always appeared to have a beneficial effect, while cold usually aggravated all the symptoms. The first suggestion of a rational treatment came from Victor Horsley (*British Medical Journal*, February 8, 1891), who, from the fact that Eiselberg has been able to save two animals from myxœdema, after removal of the thyroid had been performed, by successfully grafting portions of the excised thyroid gland beneath the peritoneum, suggested the adoption of this treatment in human medicine, and shortly afterward cases were published by Horsley and Collins, where more or less improvement followed the transplantation of portions of thyroid gland of sheep in myxœdema. The permanency of the relief is thought to depend upon the vitalization of the gland, though immediate benefit was often noticed, explainable by supposing that it was due to absorption of the elements of the gland. In 1891, G. R. Murray (*British Medical Journal*, October 2, 1891) suggested the employment of thyroid juice by hypodermic injection. The juice was prepared from the gland of a freshly killed sheep, by mincing and covering with 1 c.c. of equal parts of glycerine and 0.5 per cent. carbolic-acid solution. After soaking for twenty-four hours, a turbid pink juice can be obtained by squeezing through a cloth, which is to be given in two equal doses during the week. Subsequently the dose can be given less frequently.

A number of observers, chiefly in England, claim to have had good results from the employment of this method, of which various modifications have been suggested. Recently patients have been fed with the gland minced and raw, with satisfactory results. As to the permanency of the cure, either by feeding or by transplantation, it is yet too early to speak with certainty in so chronic and persistent an ailment, but immediate benefit has been almost always marked. It has not yet been ascertained whether the thyroid treatment is of any benefit in cases of endemic cretinism and idiocy in young persons.

Tetany.—The association of this condition with myxœdema is a matter of considerable scientific interest, as the nervous symptoms of myxœdema have many points in common with tetany. True tetany has not, however, been directly traced to disorders of or operations on the thyroid gland.

Exophthalmic Goître.—A large number of clinical and pathological studies in this puzzling disease have confirmed the view that it is a disorder of the nervous system, and that the thyroid enlargement merely forms part of a wide-spread vaso-motor change. In a few cases the condition has, however, been complicated by myxœdema, pointing to a disturbance in the function of the thyroid. Whether the disturbance is a toxic one, or due to a local nervous lesion (medulla oblongata? cervical sympathetic?), is not yet determined with accuracy.

The similarity in nervous symptoms existing between Graves' disease, myxœdema, tetany, and acromegaly, has not yet received a satisfactory explanation, but it is difficult to avoid imagining that it depends upon definite disturbances of nutrition, due to the presence of an abnormal chemical product in the system.

F. X. Dercum has described a rare form of painful lipomatosis under the name of "Adiposis Dolorosa" (see page 15 of the present volume), in which there were distinct anatomical changes found in the peripheral nerves. Although in two cases the thyroid showed marked alteration, induration, and atrophy with calcification in one case, and enlargement with calcification in the other, the characteristic nervous symptoms of myxœdema were absent. *Wyatt Johnston.*

TOES, DEFORMITIES OF THE. HAMMER-TOE.—A certain number of these cases present themselves for treatment while it is yet possible to manually correct the deformity; in such cases, relief may usually be obtained, and the progress of the deformity checked, without operative treatment, by mechanical means. A stiff leather insole, the full width and length of the corrected naked foot, has slits cut in it at the divisions of the toes, and through these a ribbon, or tape, is passed, carried over the dorsum of the toe, or toes, and made fast underneath. The posterior portion of the sole is held to the foot by a ribbon, or strap, across the instep. The insole is worn inside the stocking, and its use requires a broader-toed shoe than that generally worn. *John Ridlon.*

TOLIPYRINE. This substance has been very recently introduced as an antipyretic and antineuralgic of some value. It differs from antipyrine only in the substitution of the methyl group, CH_3, for one atom of hydrogen in the phenyl group. It is a white crystalline powder very similar to antipyrine in its physical as well as its therapeutic qualities. The indications for its use are the same as those for antipyrine, the dose being somewhat less—one drachm being equal to one and a half drachm of the older drug. It has been used by Dr. P. Guttman with success (*La Semaine Médicale*, March 17, 1893), but has not yet been before the profession for a sufficient length of time to warrant the forming of an opinion as to its relative value.

A salicylate of tolipyrine has been prepared to which the name of *tolysal* has been given. It bears the same relation to tolipyrine that salipyrine does to antipyrine. It is a crystalline, almost colorless (faintly pinkish) substance, lustreless, and with a bitter taste. It is easily soluble in alcohol and acetic ether, but only sparingly in water and sulphuric ether. Tolysal has been investigated by Dr. A. Henning, of Königsberg, who describes it as possessing marked antirheumatic, analgesic, and antipyretic properties. In acute rheumatism particularly, but also in chronic articular and muscular rheumatism, it exerts a rapid and powerful influence. It should be given in doses of from forty-five grains to a drachm and a half in the twenty-four hours, fifteen grains being administered every two hours, or thirty grains to begin with and fifteen grains in the succeeding doses. It may be

continued for some days after the disappearance of the symptoms. As an analgesic the same dose was found to prove effective in various forms of neuralgia, especially those of rheumatic origin. As an antipyretic it has but little effect in lowering the temperature when it is normal, even in doses of a drachm to a drachm and a half; but in all conditions of pyrexia it rapidly brings the temperature down to normal, or even to a subnormal degree. It should be given in doses of fifteen grains every half-hour or every hour, with or without an initial dose of thirty grains, until a total daily dose of from one to two drachms is reached. It also assists in procuring sleep, both in conditions of pyrexia and apyrexia. It has no cumulative action, nor have any signs of a toxic effect been noticed, not even any disagreeable symptoms such as noises in the ears, digestive disturbance, excessive perspiration, rigors, or signs of collapse. This compound is also too recent to justify an estimate of its value.

Beaumont Small.

TONGUE, DISEASES OF THE. Since the original article, "Tongue," was written a by no means inconsiderable amount of literature bearing upon the diseases of this organ has appeared. Some of it has helped to simplify the subject, while some has seemed only to increase the confusion that already existed in regard to certain conditions. For this reason, and because several pathological states appeared to deserve more ample consideration than they had received, it was thought best to add the present supplementary text. The additions have been made as brief as possible, and for this reason they may appear somewhat fragmentary. The order followed is, in a general way, the same as that in which the subjects were originally considered.

Hemiatrophy has been found by Girard[1] to occur in dogs when the sensory portion of the trigeminus is cut through. From this he concludes that the trophic fibres run in the trigeminus and not in the facial nerve. Concerning the pathology of hemiatrophy Trevelyan[2] reports a case in which there was caries of the atlas and occiput articulation, with chronic basilar meningitis, and atrophy of the hypoglossus strangulated by the thickened meninges. The condition follows lesions of the intra-medullary and the intra- and extra-cranial hypoglossus.[3]

Progressive hemiatrophy is rarely seen, but it is occasionally observed in association with hemiatrophy facialis, to which it bears a close relationship. It probably depends upon degenerative neuritis of a low type.

TONGUE-TIE.—According to the statistics of the Good Samaritan Dispensary 315 cases have been treated during the past five years out of a total of 283,000 patients, 52,000 of which were surgical. This would make a proportion of one case of tongue-tie to each thousand patients, and six to each thousand of surgical cases. In a very large percentage of cases brought for treatment by over-solicitous mothers there is scarcely any shortening of the frenum or other abnormality requiring treatment.

Glossoplegia, associated with one-sided cephalalgia, and possibly attended with symptoms usually referred to intracranial disease, may be relieved by the free use of iodide of potassium even in the absence of any specific history. It may be secondary to bilateral lesion in the cerebral hemispheres, when it goes by the name of pseudo-bulbar paralysis. It is the first symptom in true progressive bulbar paralysis. Speaking becomes indistinct, the tongue cannot be elevated, and protrusion is effected to a slight degree only. Characteristic furrows or wrinkles develop upon the dorsum. Galvanism applied to the neck seems to do some good.

Acromegaly with great enlargement of the tongue has been observed, and in two recently reported instances the organ was so increased in size as to be of serious inconvenience in the mouth.

Myxœdema may be attended with enlargement of the tongue, which is described as being broad, flat, and square, and nearly filling the mouth.

MACROGLOSSIA.—This usually congenital form of enlargement has been shown to be a lymphangioma of the tongue. Nota[4] thus classifies the methods of operation usually employed for its cure:

A, Simple scarification. B, Compression, direct or indirect. C, Incision in V-shape. D, Amputation. E, Ignipuncture. F, Electrolysis and galvanocautery.

The lingual arteries may be tied upon both sides as recommended by Demarquay, and practised successfully by Nota in one case, or the protruding portion may be divided with scissors and each half removed separately with the écraseur, as in a case reported in the *China Med. Miss. Journ.*, June, 1892. Brück[41] has written an interesting paper on the subject.

Clonic spasm is a rare affection observed by Erb, Berger, Remak, Wendt, and Seppilli.[5] The tongue may be protruded against the will, pushed forward against the dental arch, or show involuntary muscular contractions on one or both sides. Clonic spasm is seen in hysteria and in the epileptic seizure. Bromide of potassium, electricity, etc., are recommended. The condition may be looked upon as a neurosis of the hypoglossus.

Chorea-like movements, limited to the tongue, have been reported[6] as occurring in hemiplegia to the extent of interfering with speech. The movements grow less as the paralysis improves.

Tonic spasm is also seen in hysteria, and in other cases where the cause is unknown, probably from reflex irritation.

Glossitis superficialis was described by Möller[7] in 1851, and again more recently by Michelson.[8] The process is somewhat chronic and difficult to cure. It is a rare disease and usually occurs in women. Irregular red spots and hyperæmic, enlarged papillæ, with loss of epithelium, appear for the most part upon the sides and tip of the tongue, and may occasion pain of a burning character, which is intensified by eating and speaking, and often affects the patient's disposition so as to cause moroseness or hysteria. There is no pathological secretion and no ulceration. Regarding the etiology, digestive disturbances appear to have been present in the cases reported.

Joseph[9] observed an instance which had begun two and a half years before, after eating a dish prepared with an abundance of mustard.

Hahn[10] reports one which began near carious teeth, but did not disappear when these were extracted.

The diagnosis might be confounded with neuralgia from the occasional sharp character of the pain. Molènes reports three cases under the title, "*glossite épithéliale en paires*," all in arthritic subjects and associated with dyspepsia.

Treatment is unsatisfactory. More can be accomplished by attention to the digestion than by local measures. Joseph secured the best results with fifty per cent. lactic-acid solution, rubbed well into each patch separately. Hahn secured temporary relief with ten per cent. menthol solution.

The writer has treated one case of this nature which, in addition to the intensely red and painful patches, enlarged papillæ, etc., presented a yellowish-white pseudo-membrane, which dipped down into the numerous deep fissures of a naturally fissured tongue, and also occurred upon the mucous membrane of the cheeks, in a young lady. The disease had appeared after eating much candy, the digestion being at the same time somewhat faulty. Chromic acid, nitrate of silver, and various mouth-washes gave but temporary relief, and the extremely annoying condition has persisted for three years and has been seen by a number of physicians here in New York. The patient is somewhat hysterical. Another case likewise associated with dyspeptic attacks, recurred at intervals for several years.

Glossodynia exfoliatu of Kaposi is thought by Joseph to be identical with the foregoing. Both may have a long course and show hysterical and hypochondriacal symptoms.

HEMIGLOSSITIS.—Up to 1885, Güterbock had been able to find but twenty instances of hemiglossitis in medical literature, including his own observations. Undoubtedly many one-sided inflammations of the tongue are due to herpes, though phlegmonous inflammatory states end-

ing in abscess formation are not unknown. In the herpetic form the territory of the trigeminus or, according to de Mussy, that of the chorda tympani, is invaded.[11]

Abscess, aside from the origin above hinted at, may be occasioned, Bamberger says, by the action of cold. Spontaneous cure after rupture is the rule, but the volume of the tongue may remain much increased in exceptional instances. If seen early, the inflammation may be reduced by the free use of ice and emollient washes.

Ulceration of the tongue may develop upon a pre- or co-existing tumor, or upon the surface of an otherwise healthy organ. Of the former variety is especially to be mentioned the ulcer of epithelioma, which is to be distinguished from those due to syphilis of the tongue and those resulting from the irritation of faulty teeth. In cancer the ulcer is in relief, resting upon a markedly indurated base, is irregular, red, bleeds readily, has ragged edges, is covered with an ichorous secretion, and occasions often severe lancinating pains and otalgia.

In chancre, the ulcer is likewise attended with an indurated base, although this at times may be very slight. The ulcer may penetrate deeply, but it occasions little or no pain or inconvenience. The borders are not perpendicular, but incline gently inward to the base. The ulcer in gumma is hollowed out, has perpendicular, or as though incised borders, sometimes suggesting that a piece had been removed with a cutaneous punch. The base is yellowish with a sloughy uneven adherent eschar-like substance. Resolution is hastened by treatment, which is not the case in cancer. The ulcer which develops secondarily upon a syphilitic sclerous glossitis or a sclero-gummous condition of the organ may be of the nature of a simple ulcer, which depends upon the mechanical conditions present and does not assume the characteristic form of gummy ulcer. Ulcers not associated with neoplasms are much more frequent than those just discussed. They may be due to mechanical and traumatic causes, to the presence of micro-organisms, to eruptive lesions such as are seen in skin diseases, including syphilis, to the breaking down of patches of leucoplasia, and to the excessive use of mercury. Ulceration produced by the constant friction against a sharp or even blunted irregularity of a tooth is a common form of the traumatic variety. Le Pileur [12] reports instances in which tongue ulcers could not be cured until the slight projections of otherwise healthy teeth against which the lesions impinged were covered with a protective apparatus made of gutta-percha. Bugnot [13] reports a similar case in which futile attempts were made for three months to heal two small ulcerations at the tip of the tongue in a nine-year-old boy, which at first sight looked like aphthous ulcers, but which occasioned such intense hyperæsthesia as to prevent sound sleep and cause much discomfort in eating. The first night after a protecting cap was placed over the lower lateral incisors, which were somewhat out of line with the other teeth, the child slept well and the ulcers disappeared without further treatment.

The *herpetic ulcer* is at first quite superficial, small, often in the form of miliary erosions, rather than ulcers, which by confluence form an irregular ulcerating surface. They follow the rupture of small vesicles. Superficial round ulcers often thickly dot the tongue in varicella, likewise from the rupture of vesicular lesions. Larger ulcers result in the same manner from rupture of full-size vesicles or bullæ in zoster, pemphigus, or hydroa. In lupus the ulcer is much the same as that of tubercle presently to be considered.

The chief *syphilitic ulcer* is the mucous patch, so common as to be an almost invariable lesion of secondary syphilis. In size it is usually somewhat larger than a lentil, for the most part round or oval, hollowed out and with a grayish-yellow base as a rule, but, as Fournier [14] says, there is nothing special in the configuration, color, or character of the border by which the mucous patch of the tongue can be always diagnosticated. Ulcerated fissures may occur in secondary and tertiary syphilis. Vertical striæ or a form of fissured mucous patch may occupy the borders of the tongue. For all of these lesions probably the most useful local application is chromic acid. I have employed it for several years in from twenty-five to seventy-five per cent. solution. It is superior to nitrate of silver for all ulcerative lesions and especially for mucous patches.

Ulcerations taking place on patches of leucoplakia, either starting from fissured lesions in the plaque, or following the detachment of a portion of its area, will have their nature indicated by the original condition, which may or may not be syphilitic.

Mercurial ulcerations have a grayish-white, sometimes diphtheroid appearance, and are accompanied by a generalized stomatitis. The breath is offensive and there is salivation. The lesions occupy the lateral borders of the tongue, which are usually indented by pressure of the teeth. Gangrene may supervene. I have recently found benefit from the local use of bichloride mouth-washes, which might lend some weight to the septic theory of mercurial stomatitis.

Tuberculous ulcer assumes constantly greater importance, and the question of its existence as a primary condition renders it the more interesting. Tubercular deposit in the glands may add to the already strong simulation of epithelioma for certain cases, and the depth of infiltration beneath the ulcer makes it necessary to remove much tissue when operation is resorted to in an attempt at radical cure. This ulcer has been observed in childhood and its nature confirmed by bacteriological examination. Dr. Robinson presented two cases at the New York Dermatological Society.[15]

In one the lesion had first appeared on the point of the tongue three years before, and although it was removed, together with the whole tip of the organ, the wound had never healed.

The second case, also in a man, was regarded as an instance of primary tuberculous ulcer, which had developed near the point of the tongue nine months previously as a hard grayish lesion, the size of a pin-head, and slightly painful to the touch. Subsequently a similar growth appeared on the opposite side, and there extended until an oval-shaped ulcer, three-quarters of an inch in length, occupied the apex. At the present time this ulcer presents the following appearance: the base is reddish, like the floor of a granulating wound and irregular, with reddish points, having grayish-yellow material between; the margin is irregular and elevated, and the edges are perpendicular, and beyond it the tongue tissue is apparently normal. Bacilli have been found in a few sections. Now, after nine months of good health, evidences of pulmonary implication are beginning to manifest themselves. One of the surest evidences that a chronic ulcer of the tongue, which is not influenced by any ordinary treatment, is really tuberculous, is the appearance, upon the surface, of the minute yellow points which Trélat, in 1870, demonstrated to be tubercles in course of development. The presence of these, together with microscopical sections of a small excised portion, and bacteriological cultures made from scrapings of the surface, furnish the only positive proof of the real nature of these ulcers. The importance of early and radical operation in primary tuberculous ulcer, so as to prevent systemic infection, need not be dwelt upon. Weir reports recurrence in five out of seven operations regarded as thorough.

In the *ulcer of lupus* there is much less pain, or it is entirely absent, and the process is much slower of evolution. Primary lupus has been observed by Leloir [16] and Clarke,[17] the former author confirming an instance by inoculation.

Lichen planus is occasionally observed in association with this disease upon the cutaneous surface, and I have seen several such cases, which have of late years been presented at the New York Dermatological Society.

Exfoliatio areata linguæ is a condition seen mostly in children, but also occasionally in the adult, whose nature is not yet wholly understood, but which is looked upon by many as a deformity rather than a disease, and is considered by some to be a physiological condition. The writer has repeatedly noted its presence in several children of the same family, starting at or shortly after birth, and

persisting for many years. While almost impossible to correct by treatment it disappears at times spontaneously. The dorsum of the tongue is covered with various-sized rounded smooth areas, from which the filiform papillæ have been shed. At the margin of the patch is almost constantly present a broad white or yellowish ring, and the color of the patch is usually of a brighter red nearest the ring. These patches increase at the periphery and wander from one portion of the organ to another, even exteuding upon the under surface where no papillæ exist, giving the *lingua geographica* appearance. It seems improper to call it a *glossite exfoliatrice marginée*, for there is no subjective symptom or evidence of inflammatory action. While no micro-organism has been demonstrated as the cause, it has the features of a parasitic affection. Unna compares it to alopecia areata, and places it among the tropho-neuroses. I have observed the condition about twenty times in some two thousand consecutive examinations of children and adults, finding it, however, in only four instances in the latter, one being in a patient with lupus of the face. Fortunately, treatment is rarely demanded, and it is of little avail.

Leucokeratoses include all white patches of the tongue due to epithelial change—keratosis, dyskeratosis, and hyperkeratosis—whether the result of syphilis, arthritism, the abuse of tobacco, alcohol, faulty teeth, or other cause. The chief importance of the condition is the great tendency it shows toward degeneration into epithelioma. It should therefore be treated and cured if possible before any sign of papillomatous change takes place, and as soon as such change is noticed operation should be resorted to. If there is a syphilitic history a thorough course of treatment should be instituted.

Leloir[18] applied to the histology of leucoplakia Ranvier's theories in regard to eleidine and showed that we must distinguish two periods in the process:

1. That in which the mucous membrane is, so to speak, transformed into skin or hyperkeratinized (a thick granular layer forming with abundance of eleidine).

2. Partial exfoliation of the plaque and consecutive inflammation with formation of fissures, exulcerations, and ulcerations—dekeratinization, characterized by the disappearance of the granular layer and of the eleidine.

Schwimmer, who first described the histological lesions of leucoplakia, advises[19] as local treatment salicylic acid, ten to fifteen grammes dissolved in fifty grammes each of alcohol and distilled water, while he has obtained no good results from lactic acid. In advanced cases, with thickening of the mucous membrane, the curette has given good results. At the same meeting De Watraszewski said he had obtained the best results from a five and subsequently a ten per cent. solution of bichromate of potash, securing after its application a soft, supple, and hyperæmic cicatrix, which, however, showed tendency to ulcerate when irritated. Leucoplakia has been observed in association with lichen planus, lupus, keratosis follicularis,[25] vitiligo,[20] and other skin diseases, but the connection is not clear.

Nigrities linguæ is a hyperkeratosis of the filiform papillæ, and especially of the horny epithelium, and was first described by Rayer in 1835. The black discoloration which gave to the condition the name of "black tongue" was long considered due to the presence of parasitic growths, but Brosin found the organisms to be a poorly developed form of *oïdium albicans*, to which he attributes little or no importance. The prevailing opinion now held is that the *lingua nigra* depends upon the development of some form of pigment whose nature is still unknown. Leviseur,[57] who reports a case, says it is probably the same pigment which Unna has shown produces the black color in comedones and ichthyosis histrix, and he still sees no reason why a fungus growth should not act very much in the same manner as a chemical preparation. I have observed as a chronic condition the lengthening and epithelial increase of the papillæ upon the dorsum, so that they would lie like a thick growth of hair, pointing outward, and I have seen such growths accidentally blackened by iron and other drugs, but have never yet met with a blackened condition which I could regard as of essential nature.

Primary erysipelas of the tongue has been reported by a number of observers, but while some[21] maintain that the organ does not become tumefied, others[22] describe the swelling to be of such a size as to prevent the mouth's being closed, with pain[23] attending every movement of the organ. Though this condition is rarely observed, there would seem to be no good reason why the streptococcus should not effect an entrance through a lingual ulcer or fissure, and implicate the tongue in an erysipelatous inflammation before making its presence known upon the skin surface, as it usually does in these cases within a short time.

Strawberry tongue is not confined to scarlatina, but is seen quite frequently in epidemic influenza, and in a mild degree of development in parotitis and some other diseases. The peculiar appearance is occasioned by swelling of the filiform and fungiform papillæ whose epithelial covering has been shed. Neumann[24] gives three stages in the strawberry tongue:

1. Swelling of the mucous membrane and cloudiness of the epithelium.

2. Desquamation.

3. Regeneration of the epithelium.

Strawberry tongue appears to be present in about eighty per cent. of scarlet-fever cases, appearing on the fourth day and lasting four days or more.

In the tongue of dyspepsia the red fungiform papillæ slope toward the tip, while in scarlet fever they are round and erect.

Varicella is almost constantly attended with lesions upon the tongue, according to my personal experience during the past few years, but as they tend to heal as promptly as those upon the skin they have little importance. The vesicle is never to be seen, but a small, round ulcer with yellow base takes its place.

Psilosis is the term employed by Thin[26] to describe a disease of the tropics attended with intestinal disorders, in which the tongue is the seat of an eruption at first almost herpetic in nature, and subsequently leaving separate areas or the whole surface bare of epithelium. Sinuous longitudinal clefts are present, and the whole organ is tender and can be protruded only with difficulty. The fissures soon heal, the patches become pale, and the surface becomes glazed. Superficial ulcers at times appear. The condition might be mistaken for syphilis, were it not for the above characteristic changes which take place.

Zoster of the tongue is reported by Fournier,[27] but the instance given is not very convincing.

Xeroderma pigmentosum. Lesions of this nature upon the tip of a child's tongue have been observed in one instance by Keating.

Urticaria.—A case is reported by Laveran[28] in which a plaque of urticaria upon the tongue aided in the diagnosis of urticaria of the throat, in a man who for three years had been subject to frequent outbreaks upon the skin. Occasionally urticaria is the cause of great swelling of the tongue, but lesions on the skin render the diagnosis clear.

Eczema of the tongue probably has no existence, but Besnier[29] thinks certain desquamations with well-defined margin have some analogy with seborrhœal eczema or eczema marginatum. It is probably the same condition described above as *exfoliatio areata*. He advises the following ointment to be applied several times daily: Cocaine, five centigrammes; balsam of Peru, boric acid, each one gramme, and vaseline, forty grammes.

Impetiginous stomatitis, in which the tongue, along with the buccal surface of the cheeks and lips, is covered with a tenacious exudation, and at times fissured, has been described by Sevestre and Gaston.[30] It occurs in debilitated infants with gastro-intestinal diseases, measles, pertussis, and impetigo. The staphylococcus aureus was found in eight cases.

Stomatitis epidemica, with œdema of the tongue, vesicular eruption, and ulceration of tongue and lips, and at times necrosis of portions of the organ from the excessive

swelling, has been reported by Siegel.[31] The disease seems to have a certain identity with the foot-and-mouth disease of domestic house animals, and at the same time it presents a certain resemblance to epidemic aphthæ in children and to epidemic scorbutus.

Dermoid tumor, of a probably unique kind, is reported by Backer.[32] The cyst protruded several inches out of the mouth, pressing down the tissues of the chin, and contained forty ounces of soft sebaceous matter. If possible, such tumors should be removed with the cyst-wall intact to obviate an inflammation of neighboring tissues, which may be severe.

Schmitt[48] describes a sublingual dermoid which was mistaken for a ranula.

Sublingual fibroma is a disease of childhood, often encountered in Southern Italy, and, since the writings of Riga in 1872, it has been known by this author's name. It is at first a small pearl-colored, painless growth upon the frænum. Fede[33] found hypertrophy and hyperplasia, especially of the papillary layer of the mucous membrane at the base of the frænum, resulting from irritation of the first two lower incisors. Riga, however, reported cases which had been observed before the eruption of these teeth. It may exulcerate and become necrotic, especially where there is concomitant systemic disease. Here the general condition must be improved while antiseptics and caustics are applied, or the ulcerating growth must be cut out with scissors.

Lipoma is not very common. Rydygier[34] reports one as large as a plum, which gave pseudo-fluctuation and was easily removed by incising the mucous membrane and shelling out the growth. This author states that Krausnick could find only fourteen instances in literature.

Kirchoff[34a] reports one as large as an egg. Two cases of congenital lipoma are to be found in the literature of the subject. Zander[49] saw an encapsulated lipoma fibrosum in a boy of three years, which had existed from birth. It protruded from the mouth and was covered with mucous membrane.

Papilloma in a child of two and a half years is reported by Coverton ;[40] it was operated upon by electrolysis and the galvano-cautery. In about three thousand consecutive tongue examinations I have seen papilloma four times, but only once of sufficient size to give annoyance and require operation. The condition is, however, comparatively common, owing to the papillary nature of the tongue and the facility with which the papillæ enlarge under irritation.

Fibroma is occasionally congenital, but otherwise not very common, judging from Williams's statistics, which show only three instances in eight hundred and eighty tongue neoplasms. Vincent saw one attached by a pedicle which gave the infant the appearance of having two tongues.

Osteoma and *enchondroma*[42] are rare, and are looked upon as degeneration changes in fibroid growths.

Angioma furnished about one per cent. of tongue neoplasms treated in the London hospitals during the past twenty years. Fischer[43] relates an instance of mixed tumor — *angioma cavernosum* and *fibroma* — for which thermo-cautery and electrolysis are advocated as the proper means of cure.

Lymphangioma cavernosum, as a congenital deformity, is illustrated in a case reported by Barker,[44] in which the greater part of the tongue was removed by operation. The condition had been aggravated by repeated attacks of acute and subacute glossitis. Examination of the excised tissue confirmed the opinion expressed under "Macroglossia," that the latter is usually due to lymphangiectasis.

Myxoma was seen in one instance in Williams's 880 collected cases.

Sarcoma of the tongue exists in medical literature to no greater extent than does lipoma. Targett[35] operated on a round-celled sarcoma which had existed for a year in a patient of sixty-one years, and Scheier[36] removed one from a patient of twenty-eight. The situation is almost invariably deep, and the floor of the mouth is most apt to be invaded. They seldom extend above the surface and ulceration is extremely rare, while concomitant glandular swelling appears late, if at all. Recurrence took place five weeks after operation in Scheier's case, but this is not to be expected if the whole growth can be removed. It is not probable that, for these cases, the view holds good that all sarcomas in muscular tissue are of syphilitic origin ; still in any given case, so long as the diagnosis is uncertain, a sufficiently thorough antisyphilitic course should be instituted. Further differentiation must be made from chronic abscess and from actinomycosis.

Actinomycosis now and then occurs primarily in the tongue ; an instance of which has recently been given by Doyen and Reussel,[37] the disease developing as a deep phlegmon at the base of the tongue, with woody hardness of the whole supra-hyoid region. Maydl[38] relates an interesting instance of probable infection from the fingers, in the person of a veterinary cattle inspector, who was in the habit of moistening the finger tips on the tongue in turning over his paper. Some time after the examination of infected cattle, the tongue began to swell, pus formed, and on examination was found to contain the characteristic yellow granules of actinomycosis. The abscess cavity was scraped out and recovery took place. The tongue is often affected in animals, and numerous nodular growths form in its substance, from the size of a pea to ten times this size. Infection usually takes place by way of the mouth, and in countries where the disease is prevalent it would not be surprising to find the human tongue more often involved than the number of instances so far reported would indicate.

It is presumable that the fungus on which the disease depends exists outside the body, on such vegetable growths as cattle feed upon, and this would account for the freedom enjoyed by carnivorous animals. Miller[64] has collected 75 instances of actinomycosis in man, which, added to the 38 previously found by Israel, make a total of 113 cases in the human subject.

Recurrent herpes of a chronic nature, differing somewhat from that described by Fournier, is recorded by Flatau[39] as affecting the lips, gums, buccal surface of the cheeks, and exceptionally the palatine vault as well as the tongue. Distinct vesicles are to be seen upon the borders of the latter, especially just back of the lingual **V**. Etiologically, the condition of the teeth, excesses of tobacco and alcohol, and in this particular case systemic depression from typhoid, must be taken into account. It is regarded as an affection of the trigeminus, but whether central or peripheric is obscure.

Hypertrophy of the follicular glands far back upon the dorsum near the papillæ vallatæ and the sinus epiglotticus, attended with some inflammation and causing the sensation of a foreign body in the throat, painful deglutition, irritative cough, dyspnœa, asthmatic symptoms, and fatigue of voice, is a condition mentioned by Schech[45] and other authors.[46, 47] The follicles are inflamed, red and swollen, and may be felt with the finger or observed with the laryngoscopic mirror lying over the epiglottis and glosso-epiglottic fossæ.

The prognosis is favorable. Treatment consists in applications of nitrate of silver, tincture of iodine, or the following :

℞.	Iodii puri	0.1–0.3
	Kali iodati	1.0–2.0
	Glycerini	20.

Syphilis may cause an acute or chronic hypertrophy in this region, as indicated by Labit,[58] in which case mercury internally must be added to the above local application.

Hypertrophy of the lingual tonsil, as the preceding condition is at times called, is an adult affection, and may reach such a degree as to suggest a new-growth or polypus. The adenoid vegetations may be removed with a snare or linear écraseur, sharp spoon, or caustics, just as similar growths in the naso-pharynx are treated. Scrofulosis, catarrhs, syphilis, and leucæmia are suggested as possible etiological factors. In differential diagnosis it must be remembered that primary carcinoma very rarely,

and much less often sarcoma, occurs so far back on the organ. Indirect examination with the aid of a mirror is necessary for a satisfactory view of the region.

Hypertrophy of the papillæ.—The filiform papillæ occasionally undergo hypertrophic change, and stand out over the dorsum like little porcupine quills. They are, however, pliable, and unless kept erect by the action of the teeth, lie flat upon the surface in the direction of the tip. Such papillæ, when covered with epithelial deposits and débris, and possibly when occupied by the fungus which Dessois [50] described under the name glossophyton, constitute the condition known as "black tongue" or *nigritius linguæ*. Ten per cent. salicylic solution in alcohol is recommended as a local wash, or a solution of bichloride of mercury, chlorate of potash, borax, or alum may be tried.

Neuralgia of the tongue is a most distressing affection, and one difficult to eradicate without operation. Fortunately it is not common. I have observed one instance of it in a lady with arthritis deformans. The paroxysms are of short duration but of frequent repetition, and the attacks may come on at intervals of a few months. The pain is usually located along one border of the organ.

Papilloma of the tongue is an occasional cause of neuralgia, but more often the lingual nerve is affected. Daily scraping of the tongue has been accused of favoring its development. A rheumatic or other diathesis may be found as a predisposing cause.

Dubreuil [51] reports a case in which he performed resection of the lingual nerve in a woman forty-five years of age, whose neuralgia had lasted for four years. She had had syphilis. The lingual nerve can be reached in three ways: 1, The intra-buccal method; 2, by an incision beneath the lower border of the jaw; 3, by trephining the ramus, or the transmaxillary method. The latter (resorted to by Linhort) was the method chosen in the above case: the nerve was divided with the thermo-cautery, and the neuralgia was cured, but the inferior dental nerve was injured in the operation—an accident to be guarded against—and the right side of the lower lip rendered insensible in consequence. Wounding of Stenon's canal or the facial artery must also be avoided.

Mycoses of the tongue remain to be spoken of. There is the *mycosis leptothricia*, which affects also the fauces, tonsils, and mucous membrane of the mouth, and forms on the tongue a fibrinous network of the leptothrix starting out from the region of the circumvallate papillæ and follicular glands, and forming a dark-colored or grayish-black membrane. Threads and tufts of the fungous growth extend over the mucous surface of the cheeks. There is scarcely any fever or systemic disturbance, and this serves to distinguish the condition from diphtheria deposits, which it may simulate. Adults have usually been the ones affected. The diagnosis is most readily established by the microscope. Treatment is best carried out by means of sublimate wash in strength of 1-200. *Mycosis sarcinica* is rare, and is distinguished by the characteristic grouping and quadrangular form.

Mycosis tonsillaris et lingualis benigna was described by Fränkel,[52] in which the follicular glands at the base of the tongue were grayish-white and swollen, without subjective symptoms.

Stomatitis mycosa or thrush, considered now by some to be due to saccharomyces albicans, is seen mostly in infants, but may also be observed in the course of a serious illness and in extreme age. While the tongue is not usually alone affected, it may be, and in all cases is largely implicated, and the first patches are usually seen upon the tip. They are small, discrete spots of grayish-white color surrounded by a very faint and narrow ring of hyperæmia. They can be brushed away mechanically, disclosing a superficial loss of tissue. Much may be done to prevent the disease in infants by proper attention to matters of cleanliness, care in washing out the mouth, and in cleansing the natural or artificial nipple before the child takes its nourishment, as well as after feeding. As treatment, boracic acid, chlorate of potash, or soda solutions may be used. Forchheimer [53] considers soda the best.

Gonorrhœal stomatitis, implicating the tongue in a state of erosion or exudation of a grayish-yellow color, is among the possibilities. Dohrn recently reported such an instance in an infant eight days old. Here the back of the tongue was chiefly affected.

Stomatitis aphthosa has recently been studied by Ollivier,[55] whose observations give support to the view originally suggested by Jagar, in 1765, that the milk of animals suffering from what is called aphthous fever is capable of producing the disease in those drinking it. The connection between aphtha and foot-and-mouth disease of cattle is strongly maintained by many European observers. Fränkel has demonstrated the presence of staphylococcus pyogenes citreus and the staphylococcus of Rosenbach, neither of which in all probability has any etiological importance. Since aphthous ulcers are attended with constitutional disturbance, the theory of a general infection seems quite tenable. The primary lesion upon the tongue is granted by many to be a vesicle which, however, is rarely if ever observed, the vesicular wall having collapsed or been rubbed off before the case is seen. Forchheimer believes that various processes, and not the foot-and-mouth disease alone (which is rare in this country), may act to produce a material which, affecting the nerve-tissues of the human body, produces the herpetic process.

As a wash the following is recommended:

℞ Iodii sulphat..... ʒ j.
Aquæ..... ʒ j.

Ageusia and *parageusia* are derangements of the special sense of taste, which is lost for such substances as sugar, salt, acids, etc., in the first, and perverted in the second. Ageusia of an incomplete character is seen in some facial paralyses and hysteria. It may also result from injury of the trigeminus or glosso-pharyngeal. Both conditions may arise from irritation of the nerves of taste, and be a symptom in catarrhal diseases.

Treatment.—Antiseptic and stimulating mouth-washes and electricity. If the cause can be found and removed, the taste will speedily return.

Glossitis, besides the forms already mentioned, may occur under a variety of conditions and present different clinical features. Without entering into descriptions, we will enumerate some of those which have been described: *Acute hæmorrhagic*, with extravasation into the connective tissue of the organ, and supposed to be due to alcoholic excesses. *Dissecting*, in which the whole dorsum is cut up into furrows and clefts, permitting food particles to be retained, fungous growths to form, and epithelial débris to be deposited, until the conditions favor inflammatory reaction and ulceration. (For the cure of this condition, antiseptic or detergent sprays and douches directed into the depths of the furrows, are more efficacious than attempts to wash the mouth in the usual way. Helmkampff [56] recommends the following to be applied four or five times daily with a brush: borax, 5.00; glycerine, 25.00.) *Erectile*, with stiff hard tongue, due to hypertrophy. *Mucous*, in which the mucous coating is slightly affected. *Papillary*, with inflammation of some or all the papillæ. *Parenchymatous*, implicating the whole substance of the tongue in hard exudative inflammation, followed at times by suppuration. *Septic*, due to infection. *Sclerous*, with cellular infiltration, and offering a superficial and a deep variety, the first having superficial indurated plaques devoid of papillæ, and of a deep-red blue; the second showing a mammillated and lobulated dorsum with the mucous membrane smooth and red, though often fissured and ulcerated.

Periglossitis sublingualis has been described as a rare condition of inflammatory œdema in the cellular tissue beneath the tongue, causing pain and difficulty in speaking and eating. The causes are unknown. Treatment consists in the application of leeches beneath the jaw.

Syphilis.—All forms of syphilis are prone to mani-

fest themselves upon the tongue, but much confusion still exists, and many questions are still unsettled, concerning the exact part played by alcohol, tobacco, and other irritants in tongue lesions in syphilitics. In conditions of sclerosis and keratosis of the organ it is often difficult to say just what are specific manifestations and what changes are due to adjuvant causes. The lingual ulcer of primary syphilis usually occupies the tip or margin near the tip of the organ, and rarely the under-surface. The base of the ulcer is apt to be considerably indurated, while the level of the sore is above that of the surrounding surface. The lesion is smaller as a rule than that upon the lip or the tonsil, while it may involve nearly the whole tip, and, in my experience, is much less frequently seen than chancre of either of the last-named situations. The subhyoid as well as the submaxillary glands are found enlarged and indurated.

Diagnosis from tuberculous ulcer, which commonly occupies the same situations, depends upon the chancre's comparative freedom from pain and its greater induration, or the characteristic cardboard-like hardness of the base. Again, the chancre is apt to be hollowed out, bowl- or crater-shaped, with sides gently sloping to the centre, while the tuberculous ulcer has irregular borders and base, and the latter shows granulations which make it uneven, while here and there at the periphery are little yellow points somewhat suggesting miliary abscesses. In doubtful cases cultures made from scrapings of the ulcer's base will render the diagnosis certain by showing the presence of the bacillus tuberculosis. From chancroid it is recognized by its red or rosy color, while the latter has a yellow base.

Treatment, by internal administration or inunction of mercury and a bichloride mouth-wash, can be instituted as soon as the diagnosis is established or has been made positive by the appearance of eruptive signs. No little confusion has arisen from the indiscriminate use of terms in describing syphilitic tongue lesions, but, if it is borne in mind that the moist papule or tubercle, the mucous patch or plaque, condylomata lata and certain opaline plaques, are for all practical purposes identical lesions, corresponding, if not coinciding, with papular or tubercular eruptions upon the cutaneous surface, and modified by the conditions of the ground on which they grow, and influenced by the moisture, heat, presence of micro-organisms, and various sources of irritation to which they are subjected in the cavity of the mouth, so as to appear under various types, the apparent differences will be readily understood. The papular type of the mucous plaque is less common than the erosive, but in one form or another this lesion is the most frequent sign of syphilis, in the period immediately following the initial sore, and in the early periods of inherited syphilis. It comes early, recurs at frequent intervals, and may become persistent and obstinate, especially along the borders of the tongue which come into contact with the teeth, and especially in those who use and abuse tobacco.

The opaline appearance of some plaques is explained by the presence of the young cells with which the serum escaping from the hyperæmic patch is charged ; and the pseudo-membrane which covers some patches is said to be the result of an excess of fibrin in this same serous exudate. Brisk friction will remove the whitened cells and membranous coating, but the latter will be quickly reproduced. These lesions of the tongue are highly contagious, and together with those of the lips and other parts of the buccal membrane, prove a fruitful source of contagion in non-venereal syphilis, making it possible for the disease to be acquired in innocence and to be possessed often for a long time in ignorance. Occasionally mercury appears to act as an irritant upon recurrent and persistent opaline plaques of the tongue, and it is not until iodide of potassium is substituted that they disappear and remain away. Several small plaques may coalesce and form an area of irregular outline upon the dorsum, sometimes almost covering its entire surface. This is seen especially in hereditary syphilis, where the mucous plaque is the most important sign of the disease, and the most to be dreaded by the wet nurse.

An analogous condition is found in the smooth, dry plaque, which Fournier has so happily termed *glossite tonsurante*, occupying any portion of the dorsum as a single or multiple lesion, and appearing along with the early mucous patches or quite late. The appearances are similar to those of the bald patches of alopecia areata seen upon the scalp, being quite smooth from loss of the filiform papillæ over a given area, while all around the papillæ retain their natural length and appearance. The color of these bald spots is bluish-gray, and this is not appreciably altered by the application of nitrate of silver, which, however, stains the surrounding papillæ and increases the contrast. Chromic acid colors the patch slightly in comparison with the surrounding tissue, but appears to materially hasten a return to the normal condition. Very similar tertiary plaques exist, though their existence is often overlooked until a resulting fissure or series of fissures has taken place in the area which has been the seat of diffuse hyperplasia. When a number of patches lie close together or have become confluent, and the interstitial connective tissue is in a state of hyperplasia producing an *interstitial glossitis*, and the resulting fissures divide the tongue tissues, possibly in various directions, the condition has been called *glossitis dissecans*. These forms are seen in late syphilis more especially, and at times seem to be only connected in an indirect way with the disease itself, and are not to be looked upon as wholly due to the specific poison, any more than are certain cases of *sclerous glossitis* or leucoplasia in those who have had syphilis. There is, however, a deep form of sclerous inflammation of the tongue which is of undoubted specific origin, produces no pain or discomfort, and is succeeded by fissuring or cleavage. Fournier finds that multiplication of the plaques and condensation by fibro-plastic deposit may take place. Organization is followed by contraction, which results in strangulation of the tissues and consequent sclerosis. In his superficial variety there are rounded indurations in the derma which appear as firm, smooth, cherry-red areas, either distinct or confluent, and tending to develop erosion, ulceration, or fissures. In his second or deep variety, swellings on the dorsum are succeeded by atrophy. The lobulated surface here presented has been compared to the surface of the liver in cirrhosis. It is considered almost pathognomonic of syphilis. The mucous membrane is smooth and of a wine-colored hue. As in the first form, furrows and fissures result from contraction of organized tissue, and may leave the tongue greatly disfigured unless treatment is prompt. Iodide is indicated in large dose, especially when gummata coexist, as is not unusual. If contraction has taken place, little can be done. It is possible, however, for papillary growths to spring up in clefts and fissures, and in a measure help to obliterate them, and such growths can be induced and stimulated, as I have convinced myself in one case, by packing the fissure with powdered aristol. This powder is also efficacious in ulcerating forms, but is difficult to keep upon the surface, and not greatly superior to chromic acid. If the case has not already received a thorough course of mercury, and does not show signs of rapid improvement under increasing doses of iodide, these inunctions are greatly to be preferred to mercury by the mouth.

Leucoplasia may exist independently of syphilis or the previous use of mercury, though both these factors enter largely into the etiology of many cases ; while in those of undoubted syphilitic base the element of tobacco and alcoholic irritation is almost constantly present.

Thus, mixed forms are probably much oftener observed than leucomas having a single cause. The syphilitic form is apt to be yellowish-white and of rather a dull hue as compared with the silvery or bluish whiteness of the non-specific kind. The latter may occasionally be found stained with the juice of tobacco. Then, too, the former is said to be often divided into little squares by crossed fissures, while the latter is more or less irregularly furrowed with superficial lines. The syphilitic form is much more readily influenced by treatment and can be cured, while recovery is rare in that due to other causes.

To be successful, local and constitutional treatment must be combined, and tobacco must be withdrawn.

The diagnosis from mucous plaque is generally an easy matter, since the latter is of much more rapid development, is usually multiple, dead-white, and not so translucent as beginning leucoplakia. Syphilitic scars may simulate the condition, but they are usually depressed, occupy the margins rather than the dorsum, and never change their location or spread.

Fissures are prone to occur in leucoplakia, causing pain in patches otherwise free from discomfort. Denuded patches and ulceration may follow the exfoliation of portions of the thickened epithelium, either from traumatisms or from spontaneous shedding of dead tissue. Since leucoma, whether in a syphilitic subject or in one who is free from the taint, is so apt to be the starting-point of carcinomatous change, the question of treatment assumes a double importance.

Treatment.—While it is possible for certain superficial, soft, pliable, bluish-white leucomas to disappear spontaneously or under local and constitutional treatment, the thicker and older plaques rarely if ever do so. There are those who maintain that every leucoplakia should be cured, if possible, even by surgical means if necessary, because of the danger from tongue cancer. While I am not prepared to admit that the resulting cicatrix and deformity, which may prove an object of irritation and be subject to many of the same dangers as was the original patch, is greatly to be preferred to a plaque which gives no trouble, still I am strongly of the opinion that all such tongues should be regularly inspected by a physician, and a radical operation undertaken at the first evidence of approaching danger. Perrin regards the best line of treatment in any case to be the total destruction of the white patch with the thermo-cautery or the galvano-cautery, and such a course seems to me much to be preferred to any attempt to remove the plaques by acids or other caustic applications.

Gumma or node is important not only in differential diagnosis from cancer, but also by reason of the fact that it may at times be the sole evidence of a specific taint, which, unless recognized and treated, may cause considerable loss of tissue.

Again, the node must be distinguished from that of tuberculosis, which is small, prominent, single, sometimes yellowish, and almost always ulcerated when observed. Deep-seated gumma may simulate a foreign body embedded in the tissues, and conversely, a tooth in the tongue has been taken for a gumma, and in the same way confusion may be caused by fatty and fibrous tumors, which, however, are quite rare. The former are apt to be lobulated, and the latter are harder and more circumscribed.

The characteristic of the gumma is that it is not sharply defined from the surrounding parts, and is often multiple, while both benign and malignant tumors are single. In doubtful cases always test by treatment before operating.

Prognosis is very favorable, and the earlier the diagnosis is made before softening the better. Phagedenic gumma is rare.

Treatment by large doses of iodide of potassium almost invariably brings about speedy resolution and cure.

Tuberous elevations located between the furrows and fissures of those tongues (in old syphilitics) which have been the seat of interstitial fibrous inflammation, and are due to the constricting effect of bands of tissue throwing the intervening tongue substance up into little mounds, must not be mistaken for gummatous formations, although to the touch they are often quite firm, and may materially soften under anti-syphilitic treatment.

Papillomatous, fungous, vegetating, or cauliflower-like growths, sometimes with ulceration at the summit, may occur, as the result of syphilis, upon the region of the tongue lying between the papillæ maximæ and the epiglottic fold. They may be scraped off with the curette and the base cauterized.

Lingual tonsil hypertrophy is found in hereditary syphilis; but it is also observed in the so-called strumous cases, and concomitant lesions or other evidence of syphilis may be necessary to distinguish it. A laryngoscope is required to show plainly the region. There are no positive symptoms by which specific hypertrophy can be distinguished from non-specific. Both give the sensation of a foreign body in the throat, affect the voice, cause fatigue in speaking, and occasion spasmodic cough. Iodine makes a good local application.

Diffuse sclerous glossitis, with much enlargement and hardening of the tongue, is rare. The surface which is free from papillæ is smooth, with red and white patches scattered over the dorsum. An instance of superficial sclerous glossitis, in which the organ appeared contracted or atrophic, and the smooth denuded dorsum was of a faint bluish tinge, was recently observed in a patient of mine who had contracted syphilis twenty-five years ago.

Disfiguring cicatrices upon the dorsum, as well as along the margins, are found upon the tongues of those who may have had no active signs of the disease for many years. They result from fissures, ulcers, and ulcerating gummata, and are permanent, excepting in so far as the possibility of their again breaking down is concerned, in which case new scars result. They present star-shaped, linear, or curvilinear, whitish, slightly raised or depressed striæ, or they may occur as more or less rounded patches.

TRANSPORTATION OF THE DISABLED ON LAND.

At the time of the publication of the article on this subject in Vol. VII. of the HANDBOOK, the principles of the carriage of the disabled were firmly fixed and no change has since been made in them. But through the labors of the medical officers of the army, the details have been revised and improved until, at the present time, a practically permanent system may be said to have been determined upon. Chief among those whose work has contributed to this result are Colonel Woodhull, Majors Smart, Heizmann, Havard, and Hoff, Captains Brechmin, Strong, Dietz, and others. The present article is an abstract of the methods now used with certain additions and modifications made chiefly by one of the officers best qualified by experience and observation to select the most serviceable; in many instances, the exact words of the manual are employed; and the writer wishes to state distinctly that he is not presenting his own work, but that of his colleagues in the medical department.

The litter has been modified somewhat, and now consists of a canvas bed, six feet long and twenty-two inches wide, attached laterally to two poles, seven and a half feet long, held apart by a jointed brace at either end of the bed, as in the Halstead litter described in the HANDBOOK, Vol. VII., p. 224. The projecting ends of the poles form handles, nine inches long on either end. The litter rests on four fixed, looped-shaped, strap-iron legs, four inches high and an inch and three-quarters wide. On the left front and rear handles, a half-round iron ring is fixed, four and a half inches from the end; between this and the canvas plays the movable ring of the sling. A cross strap with ring and snap is permanently fastened to the bottom of each pole, near the handles, the free (ring) end passing through a staple under the opposite pole. When the litter is open, the straps lie transversely under the canvas, but when it is closed, they are passed around it through the free loops of the slings, and fastened to the snaps, thus securely closing the litter.

On either end of the litter is attached a sling, made of woollen webbing, two and a half inches wide, with a leather-lined loop at one end and at the other a leather strap with buckle, the strap passing through a steel swivel, itself attached to the movable ring on the handle.

The officers of the Hospital Corps detachment are the medical officers on duty with it. The non-commissioned officers are the hospital stewards and acting hospital stewards attached. Officers and non-commissioned officers of the same grade rank according to date of commission or warrant.

In the latter part of 1891 members of the Hospital Corps, who had previously been required to enlist in the line and serve one year there before entering the Hospital Corps, were permitted to be enlisted directly. In order to give these men the military training which had previously been given in the line companies, companies of instruction were organized at certain central military stations, where recruits are given a course of training in military and professional subjects.

Applicants for admission to the Hospital Corps are required to be over eighteen and under thirty years of age, and qualified to pass the physical examination as described by Colonel Greenleaf (HANDBOOK, Vol. II., p. 738, and SUPPLEMENT, p. 650) for all recruits, with the exception of refractive errors of vision. Marriage and excessive addiction to stimulants are positive disqualifications. The pay of privates of the Hospital Corps was increased in 1892 to an average of twenty-one dollars a month, with allowances consisting of clothing, lodging, board, and medical attendance, worth at a low estimate forty dollars a month more, making the position worth over seven hundred dollars a year.

An important feature of the training of the Hospital Corps, together with the company bearers (HANDBOOK, Vol. VII., p. 224), consists of instruction in carrying the disabled. In drilling in these manœuvres the detachment is formed in single rank, privates of the Hospital Corps on the right, company bearers on the left, each class graduated in size, the tallest man on the right. Civilian classes, in rehearsing these methods, should be formed in single rank, according to height, from right to left.

The medical officer commanding stands two paces in front of the centre of the detachment, with junior medical officers, arranged according to rank from right to left, two paces in the rear. The non-commissioned officers are arranged, the senior two paces in rear of the second file from the right, the second on the right of the rank acting as the right guide, the third on the left of the rank as left guide, and the remainder at equidistant points on a line with the senior non-commissioned officer, ranking from right to left.

At the command *Fall in*, the men take their positions in line, each with his left arm akimbo, so as to preserve a certain distance from his neighbor, dropping the hand when the interval is obtained. After each man has responded "Here" to the roll-call, the senior non-commissioned officer commands *Count Fours*, which is executed in the usual manner (HANDBOOK, Vol. VII., p. 225). He then commands, *Count Squads*, at which the Nos. 1 of each squad, beginning at the right, call out the number of the squad in turn. He then reports the formation of the detachment to the senior medical officer, and takes his post.

The junior medical officers having taken their posts, the senior commands, *Right* (or *left*) *Dress*, at which all the men, with left arm akimbo, turn the head and eyes to the right (or left) and dress upon the guide. At *Front*, they turn the head and eyes to the front, and drop the left hand.

The detachment may be sized before counting fours, the senior non-commissioned officer arranging the men from right to left. The relative positions thus once obtained, the men habitually take them thereafter.

MARCHINGS.—The men are drilled in marching to accustom them to uniform movements. These marchings are performed as directed in the Infantry Drill-Regulations, except that the formation is in single rank.

To march in line the command is, *Forward, Guide right* or (*left*), *March*, changing the step by *Guide left* (or *right*), and correcting losses of step by, *Step*.

To march backward: *Backward, Guide right* (or *left*), *March*.

To march to the rear: *To the rear, March, Guide right* (or *left*).

To side step: *Right* (or *left*), *step, March*.

To change direction obliquely, *Right* (or *left*) *Oblique, March*, the original direction being assumed at *Forward, March*.

To move rapidly: *Forward, Guide right* (or *left*), *Double Time, March*.

To pass from quick to double time: *Double Time, March*.

To pass from double to quick time, *Quick Time, March*.

Turnings are performed as follows: To turn and halt, *Detachment Right* (or *left*), *March, Front*.

To turn and advance, *Right* (or *left*), *Turn, March, Forward, March, Guide Right* (or *left*).

To march by the flank in column of files, *Right* (or *left*), *Face, Forward, March,* if at a halt; if marching, *By the Right* (or *left*) *flank, March.*

To change direction in column of files, *Column Right* (or *left*), or *Column half Right* (or *left*), *March*; if at a halt, the command, *Forward*, precedes these.

Being in line to march by the flank, the command is: *Fours Right* (or *left*), *March.*

To form column of twos or files, from fours, the commands are: *Right* (or *left*), *by twos* (or *files*), *March.*

To form column of fours from twos or files, the command is: *Form fours, Left* (or *right*), *Oblique, March.*

To change direction in column of fours, the command is the same as in column of files. Being in line, to form column of fours and change direction, the command is: *Fours Right* (or *left*), *Column Right* (or *left*), or *Column half Right* (or *left*), *March.*

Being in line to march in column of fours to the front, the command is: *Right* (or *left*), *Forward, Fours Right* (or *left*), *March.*

To change the file closers from one flank of a column of fours to the other, the command is: *File Closers on the Right* (or *left*) *flank, March.*

To oblique in column of fours, *Right* (or *left*), *Oblique, March.*

To march to the rear in column of fours, *Fours Right* (or *left*) *about, March.*

Line may be formed from column of fours by, 1, *Fours Right* (or *left*); 2, *March*; 3, *Guide Right* (or *left*), or, 3, *Detachment*; 4, *Halt.* Or line may be formed by *On Right* (or *left*) *into line, March, Detachment Halt, Front*; or *Right* (or *left*) *front into line, March, Detachment Halt, Front.*

In line, to march to the rear the command is: *Fours right* (or *left*) *about, March, Detachment, Halt,* or *Guide Right* (or *left*); or *To the rear, March, Guide Right* (or *left*). If at a halt the command may be: *Detachment About, Face, Forward, Guide Right* (or *left*), *March.*

On long marches the men are relieved from the necessity of keeping in step and in silence, by the command, *Route step, March,* the regular step being resumed at *Detachment, Attention.* In cases where silence is desired the men may be permitted to march as in route step but silently by the command: *At Ease, March.*

When at a halt, the men are rested by one of four commands: *Fall Out, Rest, At Ease,* and *Parade Rest.* At *Fall out*, they may leave the ranks, not going away, but remaining in the vicinity to resume their places at *Fall in.* At *Rest* they keep one heel in place, but are not required to preserve silence or immobility. At *At Ease* they need keep but one heel in place, but are required to be silent. At *Parade Rest*, the right foot is carried straight to the rear, the left knee slightly bent, the hands clasped in front, and silence and immobility maintained. Attention is resumed from the last three positions by *Detachment, Attention.*

The detachment having halted in line, the senior medical officer commands the senior non-commissioned officer, *Dismiss the Detachment,* whereupon the junior medical officers fall out, and the senior non-commissioned officer salutes, steps in front of the detachment, and commands: *Dismissed.*

INSPECTION.—The detachment being formed, the senior medical officer commands: *Open Ranks, March, Front*; which is executed in the usual way. As the inspector approaches, the senior medical officer faces about, commands: *Inspection Arms,* and facing to the front salutes him.

At *inspection,* each man armed with a knife grasps and slightly raises the scabbard with the left hand and seizes the grip with the right hand, thumb to the rear and against the guard; at *arms,* he draws the knife quickly, raising the arm to its full extent at an angle of about forty-five degrees, the knife in a line with the arm, which he then drops naturally extended by the side, the back of the blade to the front and the point down. The junior medical officers, and non-commissioned officers draw and carry sword.

When inspected, the senior medical officer returns sword, and accompanies the inspector, the junior medical officers facing about, and standing at ease when the inspector passes to the rank.

Commencing at the right, the sword or knife, accoutrements, and dress of each soldier are successively and minutely inspected, each man, as the inspector approaches him, brings his sword or knife vertically to the front, raises the hand as high as the neck and six inches from it, guard at the height of the chin, edge to the left, the thumb on the back of the grip; after a slight pause he turns the wrist outward to show the other side of the blade, and, as the inspector passes on resumes the original position; after the inspector has passed, he returns knife or sword without command.

To *return knife,* the scabbard is grasped by the left hand, the right hand quickly raised as high as the neck and six inches in front of it, the point of the knife is then dropped and the blade sheathed.

After all have been inspected, the senior medical officer commands: *Inspection pouches,* at which the pouches are shifted under the right arm to the front, the flap opened and held up by the left hand, the non-commissioned officers hold up their dressing packets, pouches and packets being returned as the inspector passes.

If the detachment is equipped with knapsacks, they are inspected in the same manner as with infantry.

At the completion of the inspection, the senior medical officer *closes ranks* in the usual way.

When the detachment is to be mustered, the inspection is followed before closing ranks, by the command *Draw, Knife, Attention to Muster.* As the names are called, each man answers "Here" and returns sword or knife, or, if unarmed, steps forward one pace.

LITTER-DRILL.—Each "four" is a litter squad, which is marched by the same commands as a set of four, substituting "litter" for "four." No. 1 commands the squad, in his absence No. 4, and if Nos. 1 and 4 are both absent, No. 3 commands. In the absence of No. 2 or 3, their duties fall to No. 4 or 1, respectively. The squads are to be so arranged as to place a man of intelligence as No. 1, and to pair Nos. 1 and 4, and 2 and 3 in size as nearly as possible.

To obtain the litter the instructor commands,* *Procure Litter, March,* at which each No. 3 steps one pace to the front, faces in the direction of the litters, and proceeds thither by the shortest route, takes one, places it in the position of "shoulder litter," and resumes his place, first stepping through the interval one yard to the rear and facing about.

To shoulder litter, the command is *Shoulder, Litter;* the litter is lifted and laid over the right shoulder canvas down, at a slope of about forty-five degrees, being supported by the right arm, the right hand grasping the left pole.

At the command, *Order, Litter,* the litter is brought to a vertical position and dropped to the ground, being retained in position by the right hand and arm.

When not in use, litters are well disposed in stacks consisting of three litters, to which two more may be added. At the command *Stack, Litters,* each No. 3 brings his litter from the shoulder to a vertical position and steps one pace to the front; No. 3 of the first squad stands fast and the other Nos. 3 close in upon him and face to the front. Then Nos. 3 of the first and third squads advance two paces, and facing each other, lock the upper handles of their litters together; No. 3 of the second squad then locks his handles in and all lower the stack to the ground, spreading it below sufficient to make it stand firmly. The other litters are then laid on and all resume their posts. To remove the litters, at the command *Take, Litters,* the Nos. 3 close in as before, then advance to the stack opposite their respective litters, take their litter, and return to their posts.

* It has been suggested to make this command *Procure Litter, Right* (or *left*) *Face, March,* facing the bearers in the direction of the litters.

In the foregoing remarks, the litter has been managed by No. 3, alone. In those which follow, the entire squad is engaged.

At the command *Carry, Litter*, No. 3 brings his litter from the shoulder to a vertical position, and drops the upper handles forward until the litter is horizontal, with the canvas to the left; No. 2 steps forward and catches the front handles with his left hand, and Nos. 1 and 4 advance to the middle of the litter on the right and left, respectively. Nos. 2 and 3 hold the litter between the hand and the hip, grasping the lower handles.

At *Ground, Litter*, Nos. 2 and 3 stoop and lower the litter to the ground, with the canvas up. The carry is resumed by stooping and picking it up at *Carry, Litter*.

With the litter at the carry, the shoulder is resumed at the command, *Shoulder, Litter*, when No. 3 brings the litter to a perpendicular and then on to the shoulder, the other bearers stepping back into the same line with him.

At the command *Open, Litter*, with the litter at a carry, it is unstrapped, opened, and placed upon the ground, Nos. 2 and 3 standing between the front and rear handles, respectively.

At the command *Fold, Litter*, Nos. 2 and 3 step around to the right and left of the handles, respectively, stoop and raise it by the right handles; they then fold the braces and support the closed litter at the carry. At *Close, Litter*, No. 4 supports the folded litter at the centre with the canvas up; Nos. 2 and 3, assisted by No. 1, double the canvas smoothly on the top of the poles, release the free loop of the slings, which they place lengthwise along the poles, and secure all by the cross straps at each end, passed about the whole.

At the command *Form, Rank*, the bearers step into the same rank.

Posts at the litter may be assumed at any time at the command *At Litter, Posts.*

Posts are changed, Nos. 1 and 3, and 2 and 4, exchanging at the command *Change Posts, March.*

The litter being at the open with or without a patient upon it, is lifted at the command, *Prepare to Lift, Lift.* At *prepare to lift*, Nos. 2 and 3 stoop, place the slings over their shoulders with the loops upon the handles, and grasp both handles; and at *Lift* they rise erect.

The litter squad with the lifted litter march with a short sliding step of about twenty inches, and, while Nos. 1, 2 and 4 step off with the left foot, No. 3 steps off with the right, forming the "break step."

To lower the litter, loaded or unloaded, the command is *Lower, Litter*, at which Nos. 2 and 3 gently lower the litter to the ground and relieve themselves of the slings. In lifting and lowering the litter the rear bearer watches the front bearer and moves simultaneously with him.

To return the litter, the command is,* *Return Litter, March*, at which each No. 3 steps one pace to the front and faces in the direction of the place designated for the litter, proceeds thither by the shortest route, deposits it, and returns to his place in line.

While usually the interval between litter squads is sufficient, it may be increased by the commands, *To two* (or more) *paces, extend, March*, and the regulation intervals resumed by *Litters Close, March.*

A line of litters is marched like a line of fours, substituting "Litter" for "Fours" in the commands. To turn and halt, the command is, *Detachment, Right* (or *left*), *March, Front;* to turn and advance, being in line, (*Detachment, Right* (or *left*), *Turn, March;* in line of litters to form column of litters and halt, *Squads Right* (or *left*), *March;* in line, to march in column of litters to the front, *Right* (or *left*), *Forward, Litters Right* (or *left*), *March;* to march to the rear, *Litters About, March*, whereupon the litters are faced about, the squad moving as if the centre were mounted on a pivot; if the litter is closed or folded the squads may be marched to the rear by, *To the Rear, March;* each man facing about, the two bearers passing the litter handles from one hand to the other.

A section consists of two litter squads in line. Column of sections may be formed from line by the command, *Sections Right* (or *left*), *March, Front;* or *Sections Right* (or *left*), *Turn, March, Forward, March, Guide Right* (or *left*).

The advantage of this formation is that it permits the shortening of the column at the carry without increasing its front, by the commands, *Sections Close, March*, when the sections close up to one pace and the litters oblique toward one another, until close against the inner free bearers, the outer free bearers meanwhile closing in on their respective sides. The normal formation is resumed by the command, *Sections Extend, March.*

Single column is formed from column or sections, at the command, *Right* (or *left*) *by Litter, March*, performed in the same manner as *Right by file.*

Column of sections is formed from single column at the command *Form Sections, Left* (or *right*) *Oblique, March.*

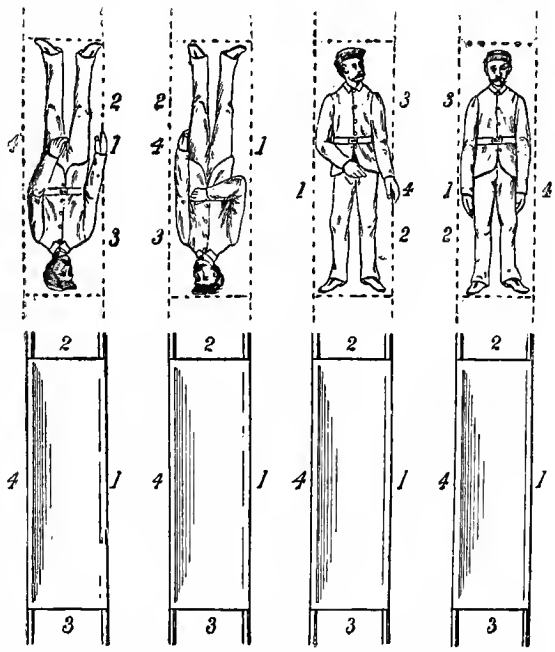

FIG. 641.—Relations in the Positions of "At Patient Posts, Right and Left."

LOADING THE LITTER.—With the litter at the carry, at the command, *Take Post to Load, March*, the squad approaches the patient and Nos. 1 and 4, in double time, take posts at his right and left side, respectively. The litter is opened and lowered as nearly as possible one pace from the patient's head, and in a line with his body. If this is impracticable, it may be placed in any convenient position.

Or, at the command, *Search for wounded, March*, each squad proceeds independently under command of No. 1. On discovering a patient, Nos. 1 and 4 proceed to him in double time, as indicated before, Nos. 2 and 3 joining them after placing the litter.

At the command, *At patient, Right* (or *left*), *Posts*, Nos. 2 and 3 take posts respectively, according to whether the command is "right" or "left," at the patient's right or left ankle and right or left shoulder; Nos. 1 and 4 invariably take posts respectively at the patient's right or left hip.

When Nos. 1 and 4 have reached their posts on either side of the patient, they search for the cause of his disability, removing his arms, accoutrements, and such portions of his clothing as may be necessary; they apply such first-aid treatment as may be required, Nos. 2 and 3 also assisting when they have arrived. In drilling, a

* The command, *Return Litter, Right* (or *Left*) *Face, March*, has been suggested as a substitute for this.

diagnosis tag is attached to the man who represents the patient, indicating the character of his disability, or the location and description of the injury, and the bearers pursue the line of conduct suggested by the disability.

The patient being ready for the litter, at the command, *Prepare to lift*, all the bearers kneel on the knee nearest the patient's feet, the right if on his right, the left if on his left, No. 2 passing both forearms under the patient's legs, Nos. 1 and 4 passing their arms under his loins and thighs, and No. 3 passing one arm under his shoulders and his other under his neck to the farther shoulder, supporting his head. In case of a fracture or other injury, the bearer nearest to it supports and looks after it. Then, at *Lift*, all collectively raise the patient slowly and gently to the knees of the three bearers, who

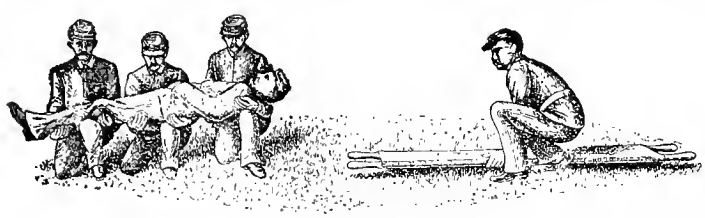

Fig. 642.—Lifting the Patient.

are in line; then the odd bearer, No. 1 or 4, arises and passing by the shortest route to the litter, grasps it by the middle, one pole in each hand, and returning, places it in front of the bearers and against their ankles.

Then at *Lower, Patient*, he stoops and assists the other bearers, who gently and carefully deposit the patient on the litter and resume their positions at litter posts.

If for any reason it is impossible to place the litter in this position, at the command, *Rise*, the bearers arise and move slowly to the litter, where they gently deposit the patient.

Passing Obstacles.—A breach should be made in a fence or wall for the passage of the litter if there be no gate or other opening, but if it becomes necessary to surmount the obstacle, at the command, *Obstacle*, Nos. 1 and 4 grasp the litter poles at the centre on either side; at *March*, No. 2 slips the litter sling from his shoulder, and, climbing over, receives the litter as it is passed over; Nos. 1 and 4 now climb over, and again seizing the litter poles, pass it over, No. 3 slipping off his sling and following. All then resume their positions and proceed.

The passage of a narrow cut or ditch is similarly effected, Nos. 1 and 4 bestriding or descending into the ditch to support and assist in crossing the litter. A wide cut or ditch may require the litter to be halted and lowered, with the handles near the edge before proceeding as before.

When it is desirable that four bearers support the litter, at the command, *By fours, Carry, Litter*, No. 1 steps back to the right, rear handle, and No. 4 forward to the left, front handle, which are relinquished by Nos. 2 and 3. The litter may be lifted or lowered in the same way by prefixing, *By four*, to the ordinary command.

Carrying the Loaded Litter up an Ascent.—The litter is faced about at the foot, and at the command, *Prepare for ascent*, Nos. 1 and 4 face inward and support the litter by grasping the poles, No. 3 adjusts his slings and grasps his handles, No. 4 steps to the near rear handle, which he grasps with both hands, while No. 2 grasps the other; No. 1 accompanies the litter as before, falling to the rear if necessary; at the command, *March*, the litter is carried up, Nos. 2 and 4 keeping their end at the height necessary to maintain the litter at a level. With but three bearers, the litter will have to be lowered before the first command. If the patient is to be carried but a short distance the original position need not be resumed until the destination is reached.

Carrying the Loaded Litter down a Descent.—Without facing the litter about at the command, *Prepare for descent*, No. 4 co-operates with No. 2 as above, but in front.

Loading with Reduced Numbers.—As previously stated, in the absence of No. 2 or 3, his place is taken by No. 4 or 1, respectively. With three bearers, the patient is lifted on the knees of two while the third places the litter; or, when the patient is to be carried to the litter, he may be carried on a two-handed seat, as described hereafter, his legs supported by the third bearer. If there are but two bearers they simply carry the patient on the two-handed seat; or, in case of fractured lower extremities it is recommended that the two bearers kneel on the injured side, raise the patient on their knees, and grasp him firmly in a comfortable position, No. 2 supporting both lower extremities, the body being supported by No. 3, around whose neck the patient clasps his hands, and they arise.

Unloading the Litter.—With the bearers at patient-posts, at the command, *Prepare to Lift*, they kneel and adjust their hands; at *Lift*, they lift him to their knees. The litter being removed at *Lower, Patient*, they gently lay him on the ground. With but two bearers the patient is removed with a two-handed seat; or, in case of fractured lower extremity, by two on a side, as in loading.

Transferring from Litter to Bed, or Litter.—With four or three bearers the litter is placed at the foot of the bed, and as nearly as possible in a line with it. After taking the patient on their knees the bearers rise and side-step gently to the bedside and lower him; or, placing the litter at the side of the bed as close as possible, the three bearers on the side away from the bed take the patient on their knees, and rising, step forward to the bedside, and with the help of the odd bearer gently lower him upon it.

The patient is removed from litter to litter by lifting the patient on to the knees, replacing the litter by the new one, and lowering him on to it.

Improvising Litters.—Litters may be extemporized from many objects, a subject that has already been fully discussed in the Handbook, Vol. VII., p. 232; but the usual military improvisation is by means of rifles and blankets.

Each squad being provided with two rifles and bayonets, carried by Nos. 3 and 4 at the "carry," and a blanket carried by No. 2, they are brought into position at the commands, *Squads, Right by Twos, March, Halt. Squads to three paces interval, Right* (or *left*), *Step, March, Halt.* The squads having thus obtained their proper positions, at *Prepare, Blanket-Litter*, Nos. 1 and 2 face about, No. 2 brings forth the blanket, which is unrolled and spread upon the ground; Nos. 3 and 4, pulling the ramrods out twelve inches—if there are no bayonets—lay the rifles under the edges of the blanket, muzzles to the front and somewhat converging, hammers in, and all the bearers roll the rifles tightly in the blanket, equally on both sides, until the space between them measures twenty inches, hammers down, and rise. At the commands, *By four*, the bearers take positions external to each rifle, facing one another, Nos. 3 and 4 opposite the butts, and Nos. 1 and 2 opposite the muzzles; at *Prepare to Lift*, they stoop and grasp the rifles firmly with both hands, and at *Lift*, slowly rise with the litter. To take this litter apart, at *Break, Blanket-Litter*, the blanket-litter being lowered, the bearers stoop and unroll the blankets on either side, return the ramrods, Nos. 1 and 2 roll the blanket and return it to its place, and face to the front, Nos. 3 and 4 bring their rifles to an order. The line is then reformed at *Form fours, Left Oblique, March.*

The blanket-litter may also be formed by rolling half of the blanket lengthwise into a cylinder, which is placed along the back of the patient, who has been turned carefully on his side. The patient is then turned over on to the blanket and the cylinder unrolled on the other side. The rifles (with bayonets fixed, if at hand) are then laid on the ground under the side edges of the blankets, muzzles to the front and somewhat converging, butts to the

head of the patient, and are rolled tightly in the blanket, equally from each side, until the body of the patient is reached, when they are turned hammers down.

REMOVING THE DISABLED WITHOUT LITTERS.—*For One Bearer.*—Four positions are taught. To bring the patient to any of these, he is first brought to the preliminary position :

FIG. 643.—Standing Astride.

Preliminary Position.—The bearer, turning patient face down, steps astride his body, facing his head, and with hands in armpits lifts him to his knees, then, clasping hands over abdomen, lifts him to his feet and places patient's left arm around his (bearer's) neck, patient's left

FIG. 644.—Preliminary Position.

side resting against his body, and supports him with his right arm around his waist.

To Lift the Patient in the Arms.—The bearer, with his right arm behind the patient's back, passes his left under the thighs and lifts him into position.

To Place the Patient Astride the Back.—The bearer shifts himself to the front of the patient, back to him, stoops, and grasping his thighs, brings him well up on the back. As the patient must help himself by clasping his arms around the bearer's neck, this method is impracticable with the unconscious.

To Place the Patient across the Back.—The bearer with his left hand seizes the right wrist of the patient, and draws the arm over his head and down upon his left shoulder, then shifting himself in front, stoops and clasps the right thigh, with his right arm passed between the thighs, his right hand seizing the patient's right wrist; lastly, with his left hand he grasps the patient's left and steadies it against his side, when he rises.

FIG. 645.—Astride of Back.

FIG. 646.—Across Shoulders.

To Place the Patient across the Shoulder.—The bearer faces patient, stoops, places his right shoulder against the abdomen, and clasps the right thigh with the right arm passed between his legs; he then grasps the patient's right hand with his left and draws the right arm down upon his left shoulder until the wrist is seized with his own right hand; lastly, he, with his left hand, grasps the patient's left and steadies it against his side, when he rises.

To Lower the Patient.—In lowering from these positions the motions are reversed.

Should a patient be wounded in such a manner as to require the motions to be conducted from his right instead of his left side, the change is simply one of hands.

For Two Bearers.—The two- and four-handed seats are formed at the command, *Form Two-* (or *Four-*) *Handed Seats, Prepare to Lift, Lift.* At the first command the two bearers take position facing each other on the right and left sides of the patient, near his hips; at the second they raise him to a sitting posture and pass their hands under him, forming the seat, passing their inner hands and arms about his neck in the two-handed seat, and rise.

Carriage by the Extremities is performed at the command, *Prepare to Lift, Lift.*

FIG. 647.—By the Extremities.

A rifle seat may be formed by running a rifle across the shoulders and through the sleeves of an overcoat, buttoned, and with buttons down, and rolling another rifle tightly into the tails, both pieces being held hammers down.

A stronger seat is formed by using the gunslings as

follows: Two men, with the slings of their rifles equally loosened as for carrying on the back, face each other with their pieces at a "present;" No. 1 seizes the sling of No. 2's rifle with the right hand, lifts his own rifle with the left hand, and passes the butt through the sling

FIG. 648.—By the Rifle Seat.

from left to right, straightening his sling as soon as his hammer has cleared the sling; No. 2 grasps the sling of No. 1's rifle with the right hand, and depressing the muzzle of his own piece, passes it through the sling he holds, from left to right, straightening the piece as the sling is cleared. The pieces now being at the original present, the butts are lowered to the ground, the left hand of each man being brought to the muzzle of his piece. No. 2 grasps the muzzle, No. 1 stoops and secures the butts. A seat 20 inches wide and 2 feet long is thus formed, on which the patient sits with his back against the rear bearer, his legs hanging over outside, and the hollow of his knees resting on the barrels.

PLACING A PATIENT ON HORSEBACK.—The help required to mount a patient depends upon the site and nature of his injuries; in many cases he is able to materially help himself. If he be entirely helpless, five men are needed to mount him, one to hold the horse, the others as bearers. If necessary the horse is blindfolded.

To load from the near side, the bearers take posts at patient's left, lift the patient and carry him to the horse, to which his body is made parallel, his head toward the tail. No. 1 takes post on the off side of the horse, ready to grasp the right leg of the patient when it is brought within his reach. Being close to the side of the horse, at the command *Mount*, the patient is carefully raised and carried over the horse until his seat reaches the saddle, when he is raised into position.

If necessary to mount him from the off-side, the bearers take posts at patient's right. The same general plan is used in mounting with reduced numbers. To dismount the patient, the process is reversed at the command, *At Patient Right* (or *left*), *Posts, Prepare to Dismount, Dismount.*

To make a mounted patient comfortable, a comrade may be mounted behind to steady him and guide the horse; or a lean-back may be provided of a blanket roll, a pillow or a bag of leaves, hay, or grass; or one may be made of a sapling bent into an arch over the cantle of the saddle—its ends securely fastened—or of some other framework, to which the patient is bound.

THE TRAVOIS.—The travois is practically a litter drawn by one animal, the rear handles dragging on the ground. It is the ordinary Indian conveyance for baggage and the sick. The travois requires but one animal and two men, one to lead the animal, and one to watch the patient and be ready to lift the rear poles when passing over obstacles, crossing streams, or going up hill.

A regulation travois consists of two jointed side-poles 17 feet long, when extended, connected by two-cross-bars, the front of which is somewhat larger than the rear, and placed six feet apart; from the cross-bars a regulation litter is suspended by straps provided for the purpose. This folds into a package nine feet long, which may be carried on the brackets of the ambulance.

A travois may be improvised by cutting poles about 15 feet long and 2 inches in diameter at the small end. These poles are laid parallel to each other, small ends to the front, 2½ feet apart; the large ends about 3 feet apart, and one of them projecting about 8 or 10 inches beyond the other. The poles are connected by a cross-bar about 8 feet from the front ends of the poles, and another about 2½ feet from the rear ends, each notched at its ends and securely lashed by its notches to the poles. Between the cross-pieces the litter bed, 6½ feet long, is filled in with canvas, blankets, etc., securely fastened to the poles and crossbars, or with rope, lariat, rawhide strips, etc., stretching obliquely from pole to pole in many turns, crossing each other to form the basis for a light mattress or improvised bed; or a litter may be made fast between the two poles to answer the same purpose. The front ends of the poles are then securely fastened to the saddle of the animal.

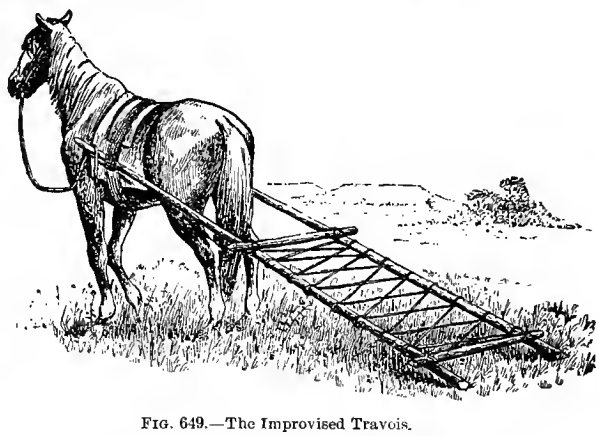

FIG. 649.—The Improvised Travois.

THE TWO-HORSE LITTER.—This is a litter with long handles used as shafts for carriage by two horses, or mules, one in front, the other behind the litter. On a good trail it is preferable to the travois, as the patient lies in the horizontal position, and, in case of fractured limbs, they can easily be secured against disturbance. The great disadvantage of this litter is that it requires two animals and three men for the carriage of each patient, one to attend the disabled man, and the others to watch over and guide the movements of the animals. The litter may be improvised in the same manner as the travois, only the poles should be 16½ feet long, and the cross-bars forming the ends of the litter-bed should be fastened 5 feet from the front and rear ends of the poles. The ends are made fast to the saddles by notches, into which the fastening ropes are securely tied.

THE AMBULANCE.—The regulation ambulance is a four-wheeled vehicle, drawn by two horses. It measures 7½ by 4 feet inside and accommodates eight men sitting, or two recumbent on litters, or four sitting and one recumbent. Its four seats can be hung, when not in use, two on each side, as cushions. The medical and surgical chests are stored in a box under the driver's seat, and there are two water-tanks under the body; outside are two brackets on each side to hold the litters.

AMBULANCE DRILL.—The litters are said to be *packed* when they are closed and put in place. The seats are

said to be *prepared* when they are horizontal, resting on the legs, and *packed* when they are hung on the sides.

Being in line at *At Ambulance, Posts*, the squad executes right by file and marches by files to the ambulance, No. 1 taking post on the left, No. 2 in the centre, No. 3 on the right of the rear of the ambulance and close to it, and No. 4 on the right of No. 3. This is the invariable position at ambulance posts, and it may be taken at that command from any position whatever.

To Prepare Seats.—With the seats packed and the squad at ambulance posts, at the command *Prepare Seats*, Nos. 1 and 3 raise the curtain if necessary, and open the tail gate, Nos. 2 and 3 enter the ambulance, No. 2 facing the front and No. 3 the rear seat of their respective sides. Each man seizes the lower edge of the seat, about six inches from the ends, with both hands and lifts it carefully to free the hooks from the upper slots, and then slips them into the lower slots; he raises the legs and adjusts them firmly in place. Then he prepares the opposite seat in like manner, and each bearer resumes at ambulance posts.

To Pack Seats.—With the seats prepared and the squad at ambulance posts, at the commands, *Pack, Seats*, Nos. 1 and 3 raise the curtain, if necessary, and lower the tail gate, Nos. 2 and 3 enter the ambulance, No. 2 facing the front and No. 3 the rear seat of their respective sides, each man releases the legs, seizes the edge of the seat with both hands, unhooks the seat and hangs it from the upper slots. After packing the opposite seat the men resume at ambulance posts.

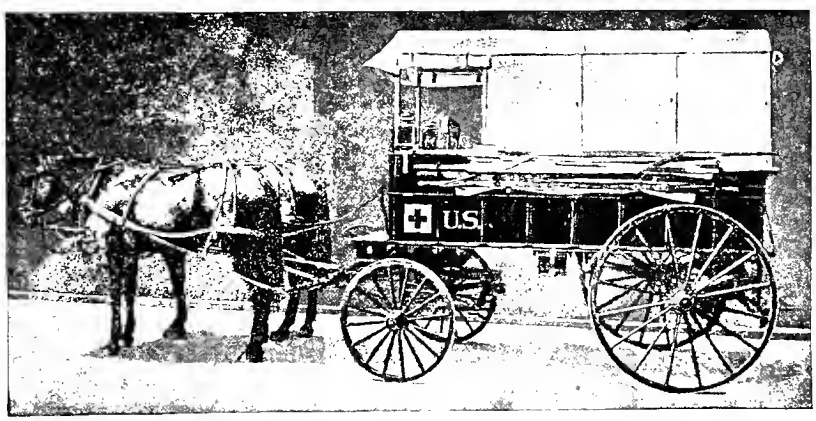

Fig. 650.—Ambulance of the U. S. Army. Pattern of 1892.

To pack or prepare seats on one side only, leaving the other side for recumbent or sitting patients, the command is, *Prepare* (or *Pack*) *Seats, Right* (or *left*).

To Load the Ambulance.—With the litter lifted, at the command *Take Posts to Load Ambulance, March*, the squad proceeds to the ambulance, executing an about on its arrival so as to bring the patient's head toward the ambulance, and a yard to the rear of it, and lower the litter.

At *Prepare to Load*, after securing the slings, Nos. 1 and 3 take posts at the patient's right and left shoulder, respectively, No. 2 facing about, and all stoop, No. 2 grasping his handles, and Nos. 1 and 3 the poles on their sides, while No. 4 opens the tail gate and sees that the ambulance is properly prepared. At *Load*, the bearers gently lift the litter to the level of the floor of the ambulance and advance to it, taking care to keep the litter horizontal; the legs are placed on the floor by Nos. 1 and 3, and the litter pushed in by No. 2, assisted by the others. This leaves Nos. 1, 2, and 3 at ambulance posts, Nos. 1 and 3 close the tail gate, No. 4 places the arms and accoutrements of the patient under the litter and takes his post.

To Unload the Ambulance.—With the squad at ambulance posts, at the command, *Prepare to Unload*, Nos. 1 and 3 raise the curtain and open the tail gate, while No. 2 grasps the handles of the litter. At *Unload*, No. 2 draws out the litter, assisted by Nos. 1 and 3, who facing inward, support the poles until the inner handles are reached. The litter, carefully kept horizontal, is lowered with the head a yard behind the ambulance, No. 4 closes the tail gate, and all take posts at litter.

To Load with Two Bearers.—The bearers seize the poles on either side and pass the litter into the ambulance. To unload, each one seizing a handle, they draw the litter out, grasping it on the sides as near the middle as possible and lower it.

The right side of the ambulance, unless otherwise directed, is invariably loaded and unloaded first.

If desired to load feet first, the command take posts to load is preceded by, *By Fet*, Nos. 1 and 4, and 3 and 2, exchanging functions.

An important part of the Hospital Corps drill is concerned with the pitching and striking of the tents composing the Field Hospital. This is done according to a uniform method and in concert.

They are also taught to pack and load pack-mules with the medical and surgical chests. *James E. Pilcher.*

TRICHLORACETIC ACID. This is one of three chloracetic acids produced by the substitution of chlorine for hydrogen atoms. In trichloracetic acid three atoms of hydrogen of acetic acid are replaced by three of chlorine. Its chemical formula is $C_2Cl_3O(OH)$. It may be prepared by introducing a small quantity of acetic acid into a bottle containing chlorine gas and exposing it to the sun's rays for several hours. It is a colorless crystalline salt, deliquescent and freely soluble in water, alcohol, and ether; it has a faint odor and a sharp caustic taste.

This acid is now used as a very convenient and delicate test for albumin in the urine. Its application is very simple, a crystal is to be dropped into the urine, where it rapidly dissolves and produces a cloudiness if albumin is present. A saturated solution may also be used, a few drops being allowed to fall upon the surface of the urine: at the point of contact a cloudiness is at once observed.

This test was proposed by Boymond (*Répert. de Pharm.*, October, 1889), and has been endorsed by numerous observers during the past few years. (*Johns Hopkins Hosp. Bullet.*, February, 1890.) (*Lancet*, March 21, 1891.) The reaction is very prompt and does not require to be confirmed by heat, as peptones are not acted upon. The only danger to be guarded against is the presence of an excessive amount of urates, which will cause a similar cloudiness. This, however, is very slow in appearing and may be overcome by diluting the urine with water.

The chloracetic acid has also been recommended as an escharotic to replace chromic acid. The advantage of this cauterization is that the effects are very localized and do not extend into the surrounding soft tissue. It has been used with success in the treatment of venereal warts, papillomata, and other cutaneous growths. It is used pure, a crystal being placed upon the part, which produces its effect at once. A dry, white, adherent scab forms, which detaches itself after a few days without causing any reaction whatever, and leaving a raw surface which rapidly cicatrizes. A single application may be sufficient for small growths, while for larger ones it may be necessary to repeat the application several times. These are not very painful, and may be rendered painless by the use of cocaine. Nævi are also reported to have been cured by three or four applications, the cicatrix remaining being

very superficial and hardly noticeable. It has also been used successfully in the treatment of chronic inflammations and hypertrophied conditions of the mucous membrane of the nose and throat. It is employed as an escharotic or as an astringent application. For the latter purpose a solution is prepared by dissolving the acid in an equal quantity of glycerine and adding a small amount of iodine and iodide of potassium. In chronic gonorrhœa it has been used by applying it directly to the source of the trouble by the aid of an endoscope.

Beaumont Small.

TRIONAL AND TETRONAL. These two hypnotic compounds have now been before the profession for two or three years, but are very rarely employed, as they have not proved to be superior to sulphonal, which they were introduced to replace. They are closely allied to sulphonal, being formed by substituting ethyl groups for those of methyl. In sulphonal there are two ethyl and two methyl groups; in trional an additional ethyl group replaces a methyl group; and in tetronal the two methyl groups are replaced by two of ethyl. The following formulæ explain the differences in their construction: Sulphonal, $(CH_3)_2\ C\ (So_2C_2H_5)_2$; trional, $C_2H_5CH_3C\ (So_2C_2H_5)_2$; tetronal, $(C_2H_5)_2\ C(So_2C_2H_5)_2$.

These two drugs are the result of a series of experiments for the purpose of determining upon which of the radicles the therapeutic action of the several sulphones depended (*British Medical Journal*, January 11, 1890). The sulphur-containing radicles were generally supposed to be the active element, but it was found that these had little influence, while the various compounds were more or less active, according as they contained a greater or smaller number of the ethyl groups. Sulphonal with two ethyl groups possessed a certain hypnotic action; when the number was increased its therapeutic power became greater, and when fewer groups were introduced it became correspondingly less. To the compounds containing three and four groups, respectively, the names tri- and tetronal were given, the title indicating the number of groups present. They both form in lustrous, tabular crystals; soluble in alcohol, but only slightly so in water—trional to the extent of one part in three hundred and twenty; tetronal, one in four hundred and fifty; the former melting at 76° C., the latter at 85° C. The taste of both is bitter, somewhat resembling camphor.

Clinical experience has shown that the relative activity of the two compounds to sulphonal and to one another, is not what was to be expected from the early theoretical and experimental reports. Both have been found to possess valuable hypnotic properties, but not superior to sulphonal; the strength, also, is not materially increased, as the quantity required is almost as great as that of sulphonal. They, however, often prove serviceable when sulphonal has been given without producing any effect. The one advantage that is evident, is a greater freedom from any undesirable after-affects or toxic action. Compared with one another it appears that the trional is really more active than tetronal, though the difference is not very great. They both have a valuable sedative as well as hypnotic action, and have proved of service in the treatment of the insane. The dose of each ranges from fifteen to sixty grains, and their best effects are obtained when administered in an abundance of hot water, about half an hour before sleep is desired. They have no analgesic action, and do not exercise any effect when the sleeplessness is due to pain. *Beaumont Small.*

TUBERCULIN AND TUBERCULOCIDIN. When Robert Koch announced, in an address before the International Medical Congress in Berlin, in August, 1890, that he had discovered a substance which conferred on animals experimented with an immunity from inoculation with the tubercle bacillus, and which arrested tuberculous disease, a degree of enthusiasm was aroused in the medical profession such as perhaps had never been witnessed before. Although the announcement was premature, the sterling character of Koch, and his brilliant scientific work, led the profession to the belief that the discovery would be even more far-reaching in its therapeutic value than the modest statements of the author claimed.

When Harvey demonstrated the circulation of the blood, his teachings were vigorously opposed by most of the older men of the time; and when Jenner's observations and experiments led him to advocate universal vaccination as the only means of eradicating that dreaded scourge—small-pox—he found his views largely opposed both by the profession and by the public. Quite different was the reception of Koch's recent discovery. Scientific medical men throughout the world were not only willing but anxious to fully test the therapeutic value of this new remedy.

That the hope entertained by Koch, as well as by the whole civilized world, has not been fulfilled, is a disappointment shared alike by all; for we must admit that we have no remedy for the malady which annually carries off a larger number of our population than any other disease—consumption.

Koch is, however, continuing his investigations, and it seems reasonable to hope that his efforts may yet meet with success. If this result is to be realized, however, it must be attained through patient research, and not by thoughtless acceptation, or hasty rejection. Koch's first publication appeared in the *Deutsche medicinische Wochenschrift*, November 14, 1890, and was published on the following day in the *British Medical Journal*, and in the *Medical News*.

Definition.—Tuberculin is a concentrated glycerine-extract of tubercle bacilli. It was at first called *Koch's fluid*, and later *Koch's lymph*. It is now known almost entirely by the name *tuberculin*, although the term *paratloid* is also sometimes applied.

History.—The discovery of tuberculin was entirely synthetical. Koch had observed that after injecting healthy guinea-pigs with tubercle bacilli, hardening and ulceration followed at the point of inoculation; the ulcer remaining unhealed up to the time of the death of the animal. If at the time of inoculation the animal was suffering from tuberculous disease, the changes were altogether local. At the seat of injection the epidermis became necrotic and was finally thrown off, leaving a rapidly healing ulcer.

If, however, instead of being fully active the cultures of bacilli were weakened in various ways, as by exposure to cold, heat, or to various chemicals, and then suspended in water and injected, the result was quite different. In healthy guinea-pigs the only effect was local suppuration, whereas tuberculous animals were killed by injections of even small doses in from six to forty-eight hours.

If the solution was further diluted and injected at intervals of from one to two days, a notable improvement in the condition of the animal took place, leading ultimately to its recovery. It was found that tubercle bacilli so injected did not spread, and it therefore seemed certain that the effect observed was due to soluble substances that had been taken into the circulation. These results were so uniformly observed in animals, that Koch was led to use the remedy in tuberculous individuals.

Preparation.—An infusion of veal is prepared in the ordinary way, and made weakly alkaline; to this is added one per cent. of peptone, and four and a half per cent. of glycerine. The best culture vessel is the flat-bottomed Ehrlenmeyer flask, in which is placed from thirty to fifty cubic centimetres of this fluid. The latter is inoculated with a small scale of the seed culture-material, which is allowed to float on the surface, and then incubated at 38° C.

The colonies of bacilli gradually form thick, white crusts, which at the end of six or eight weeks slowly settle to the bottom of the vessel. The cultures used for extraction must be fully ripe—from six to eight weeks old; they must be absolutely pure, to insure which, each vessel should be examined microscopically. The fluid culture medium extracts a considerable portion of the activity of the cultures. The pure cultures so prepared are evaporated in a suitable vessel over a

water-bath to one-tenth their original volume; they are then kept for an hour at a temperature of about 100° C. in order to kill the tubercle bacilli, which are then removed by filtering the fluid through a clay or silica filter. The fluid so prepared contains from forty to fifty per cent. of glycerine, which preserves it from decomposition, so that the remedy remains active for a long time.

A purified tuberculin has been prepared by Koch by precipitating the original fluid with sixty per cent. alcohol. Solutions of this precipitate in fifty per cent. glycerine are entirely stable. This preparation is forty or fifty times as strong as the crude tuberculin, but in practice it did not appear to present any advantages over the latter.

Test.—Before being sent out tuberculin is injected into tuberculous guinea-pigs. It has been found that 0.5 gramme kills with certainty. This requirement is therefore fulfilled before the remedy is put on the market.

Physical Properties.—The remedy is a brownish, transparent liquid, with a slightly saline taste, a specific gravity of 1.150, and a faint odor suggesting that of extract of beef. It does not tend to undergo decomposition. For use the fluid must be more or less diluted, and when so prepared putrefactive changes occur with the development of bacterial growths, unless special measures be employed. To render the diluted fluid stable it must be sterilized by heat and preserved under a cotton-wool stopper, or, more conveniently, prepared with a one-half per cent. solution of carbolic acid. It is probable that the strength of the drug is weakened by the action of heat or of carbolic acid, and therefore freshly prepared solutions should always be employed.

Chemistry.—The fluid is always alkaline in reaction. Chemically it seems allied to the albumoses, from which, however, as well as from toxalbumins, it differs in two important particulars: first, in withstanding high temperatures without losing its properties; and, second, in passing easily and quickly through the dialyzer. The active principle, which perhaps is present in but a fraction of one per cent., can be precipitated from the impure extract by absolute alcohol, not in a pure state, however, but associated with insoluble extractive substances. According to Koch, the active principle is neither an alkaloid nor a ptomaïne, but is allied to the albuminoids (*Deut. med. Woch.*, 1891), and gives the following albuminoid reactions: The biuret reaction, Adamkiewicz's reaction (glacial acetic acid and concentrated sulphuric acid); Millon's reagent causes a white precipitate which changes to a reddish color on being heated. The active principle is isolated with great difficulty, as it rapidly undergoes chemical change.

Tuberculin is completely precipitated by phosphotungstic acid, acetate of iron, and ammonium sulphate. With sixty per cent. alcohol, it gives a flaky white precipitate. An aqueous solution of picric acid causes a flaky precipitate which redissolves on the addition of heat, and again separates on cooling; nitric acid gives a precipitate which increases in density on standing, and when heated the solution turns yellow, becoming brownish-red on the addition of sodium hydrate. Acetate of lead causes a cloudiness, but no precipitate. Crookshank (Klinische Jahrbuch, 1891) gives the following reactions: alcohol in excess, a turbidity; phosphotungstic acid, a white precipitate; potassic bismuthic iodide, a slight orange precipitate; potassic ferricyanide, after standing a few minutes, gives the Prussian-blue test on the addition of ferric chloride; iodine in iodide of potassium, after standing, an amorphous precipitate; phosphomolybdic acid, a yellow precipitate; a blue color on the addition of ammonia, which disappears on boiling.

The researches of Dr. William Hunter (*Brit. Med. Jour.*, vol. ii., 1891) indicate the following as the chief constituents of tuberculin, named in the order of their importance and the relative amounts present: 1. Albumoses, chiefly proto-albumose and deutero-albumose along with heteroalbumose, and occasionally a trace of dysalbumose. 2. Alkaloidal substances, two of which can be obtained in the form of the platinum compound of their hydrochlorate salts. 3. Extractives; small in quantity and of unrecognized nature. 4. Mucin. 5. Inorganic salts. 6. Glycerine and coloring matter.

The following substances appear from these observations to be absent, namely: serum albumen, globulin, and peptones.

Brieger and Proskauer (*Deut. med. Woch.*, 1891) obtained from 16.65 to 20.46 per cent. of ash, consisting almost entirely of phosphate of potassium and magnesium. These observers give as the average composition of three samples examined, carbon, 47.61 per cent.; oxygen, 7.62 per cent.; nitrogen, 14.54 per cent.; and sulphur, 1.15 per cent.

Physiological Action.—Introduced into the stomach the remedy produces no effect whatever; it is therefore necessary to administer it subcutaneously. Man is much more sensitive to the drug than the guinea-pig, in proportion to the relative weights. In a healthy guinea-pig the injection of two cubic centimetres of the undiluted liquid was without visible effect. In a healthy adult person, 0.25 cubic centimetre administered in the same manner, was sufficient to produce a marked reaction.

Koch injected into his own arm 0.25 cubic centimetre of the remedy, and describes the symptoms which resulted as follows: From three to four hours after injection there was a drawing sensation in the extremities, weakness, inclination to cough, and difficulty in breathing, which rapidly increased. In the fifth hour there appeared an unusually severe chill lasting an hour; this was accompanied with nausea, vomiting, and a rise of temperature to 39.6° C. (103.3° F.). In about twelve hours all these symptoms decreased, the temperature became lower, and on the following day was again normal. Heaviness and debility lasted for some days, and the seat of injection remained somewhat painful and reddened during this time.

The minimum dose that will produce any effect in a healthy man, as demonstrated by numerous experiments, is about 0.01 cubic centimetre, which is equal to one cubic centimetre of the one per cent. solution. The usual effects of this dose are slight pains in the members and a transient debility. Occasionally the temperature rises to 38° C. (100.4° F.). The same effects are noted after administering the remedy to individuals suffering from diseases other than those of a tuberculous nature.

Geissler (*Wratsch*, No. 21, 1891) has injected healthy rabbits with tuberculin, killing them after ten injections, and comparing at the same time the condition of the various organs of the tuberculinized with that of the same organs in healthy animals. His studies show in the tuberculinized animals the following changes: In the liver, evidences of hyperæmia and localized patches of parenchymatous degeneration. The heart-muscle showed cloudy swelling, with hyperæmia and granular degeneration of the muscle-fibres. The changes in the kidneys corresponded with those seen in the heart. The spleen was markedly hyperæmic.

Action on Tuberculous Individuals.—If, however, 0.01 cubic centimetre is administered to a person suffering from a tuberculous affection a marked general, as well as a local, reaction follows. There is usually a chill, the temperature rises to 39°, 40°, or even 41° C. (105.8° F.); at the same time pain is experienced in the extremities, there is a desire to cough, a feeling of great debility, and frequently nausea and vomiting. Sometimes a slight icterus is to be noted. In rare cases a measle-like exanthem has been observed on the neck and breast, and still more rarely a scarlatiniform eruption has followed the administration of the remedy.

The reaction begins as a rule four to five hours after injection, and lasts from twelve to fifteen hours. Exceptionally it commences later and then runs a milder course. The patients are surprisingly little affected by the attack, and as soon as it is over are relatively well, usually as well as before the injection. Some express themselves as feeling better than before.

The local reaction can be best observed in those patients presenting external tuberculous affections. In the case of lupus, for example, the changes that take place are so characteristic, and show in so remarkable a manner the

specific effect of the drug, that a description of these in this affection will render a repetition in other tuberculous troubles unnecessary. Some hours after the injection has been made the lupus points become reddish and begin to swell, usually before the beginning of the chill. During the fever the swelling and discoloration increase and may finally reach a high degree, so that the lupus tissue in places assumes a brown-red color and becomes necrotic. Frequently the swollen brown-red patches have a whitish border, nearly a centimetre broad, which again is surrounded by a broad, highly reddened halo. As the fever declines the swelling begins slowly to decrease, so that in two or three days it may have disappeared, the lupus patches having become covered with crusts from the oozing and drying of serum. After two or three weeks these scabs fall off, leaving in favorable cases a smooth red scar beneath. The healthy skin is unaffected, but lupus points that were before invisible become apparent after the administration of the remedy. Less striking reactions, but none the less characteristic to the eye and touch, take place in cases of tuberculosis of the glands, bones, and joints.

The remedy acts upon the living tuberculous tissues in the body, but does not affect the bacilli. On dead tissue, such as caseous masses and carious bones, as well as upon tissue which has already been destroyed by the remedy, it has no effect.

It is possible, and in fact necessary, rapidly to increase the dose of the remedy, as the patient fails to react to the smaller quantities, so that in a few weeks many times the original dose may be given. This is explained by Koch by supposing that after each injection a certain amount of tuberculous tissue has been destroyed, whereby less remains to be acted upon.

Botkin (*Deut. med. Woch.*, 1891) has studied the blood after injections of tuberculin in tuberculous individuals, and has arrived at the following conclusions: (1) After tuberculin injections an acute leucocytosis is observed, in which all forms of white blood-corpuscles participate. (2) The day after the reaction the number of the leucocytes in the blood falls rapidly, and probably the greater number of the same are destroyed. This may be inferred principally from the increase in the number of blood plaques. This appearance coincides in time with the very frequently observed maximal decline in temperature after the tuberculin injections; in this respect being analogous to the blood crisis of many acute infectious diseases which are accompanied by fever. (3) The tuberculin reaction in the blood can also happen in the cases in which the temperature does not rise. (4) The increase in the eosinophil cells in the blood can not only happen in chronic diseases of the skin, but also in acute, quickly disappearing exanthemeta which appear as complications in many of our therapeutic interferences.

In analyzing the effect produced by tuberculin, Hunter concludes (*British Medical Journal*) that tuberculin owes its activity, not to one principle, but to at least three, and probably more different substances; that the fever produced by tuberculin is absolutely unessential to its remedial action. The same holds true, he believes, with regard to the inflammation produced by it. Inflammation is not absolutely necessary for the manifestation of its therapeutic effect. It is in some cases, however, beneficial, and helps under certain circumstances the action of the curative agent. Its remedial and inflammatory actions are connected with the presence of certain of its albumoses, while its fever-producing elements are chiefly associated with substances of non-albuminous nature.

Amann (*Centralbl. f. Bakteriologie und Parasitenk.*, 1891) found in examining a large number of patients that the quantity of expectoration and the number of bacilli were increased after reaction had occurred. He also confirmed the observations of others, that the bacilli appeared broken and took the stain but poorly.

The expectoration is usually increased at first, and is sometimes blood-tinged. In the favorable cases it gradually becomes mucous and later disappears; with the change from the purulent to the mucous condition the bacilli diminish in number and finally are absent.

Hoppe-Seyler (Virchow's *Archiv*, Bd. 128, Heft 1), writing on the effect of tuberculin on the formation of the coloring matter of the bile, states that after injections of tuberculin, polycholia is developed, manifesting itself by an icterus and an increased secretion of urobilin. The icterus is due to the destructive effect of the tuberculin upon the coloring matter of the blood, while the increased secretion of the urobilin to all appearances results only when the organism reacts after the injections, and is in direct proportion to the degree of the reaction.

Therapeutic Uses.—It was originally expected by Koch that tuberculin would be invaluable in uncertain cases, as a means of diagnosticating between tuberculosis and other affections which simulate it; but much more important was supposed to be its curative power in all forms of tuberculous diseases. It was believed also that with his remedy it would be possible to determine accurately when all tuberculous tissue in the body had been destroyed.

With regard to its use for diagnostic purposes, although its action is positive in the large majority of cases, it is asserted by competent observers that in rare cases of undoubted tuberculous disease, reaction does not occur. Eber (*Centralb. f. Bacteriolog. und Parasit.*, 9 and 10, 1892) has collected the results of injections of tuberculin in 247 cattle for diagnostic purposes. In 134 animals, the characteristic reaction occurred, and in 113 the result of the injection was negative. Of the 134 showing reaction, 115, or 85.82 per cent., proved to be tuberculous after killing, and 19, or 14.18 per cent., non-tuberculous. Of the 113 in which no reaction occurred, 101, or 89.38 per cent., were found after killing to be free from tuberculosis, while 12, or 10.62 per cent., were tuberculous. In a total of 247 cattle inoculated with tuberculin for diagnostic purposes, the evidence thus gained was confirmed by post-mortem examination in 216 cases, or 87.45 per cent. In 31 animals, or 12.55 per cent., the results of the inoculations led to conclusions which were at variance with the post-mortem findings.

The supposed curative effect of tuberculin has been much more disappointing. During the early weeks of the use of the remedy, cures of all forms of tuberculous affections were being reported by observers; but, unfortunately, prolonged observation of these cases has shown the beneficial results to have been apparent rather than real. The temporary improvement which occurs in the course of all forms of tuberculosis, particularly of the pulmonary variety, under any form of treatment, is a matter of common observation, and was in the cases of those receiving the tuberculin treatment but a repetition of the experience with hosts of quasi-remedies. Koch realized this to be true early in his experiments, for he says, "In many cases I have been convinced that the care which the patient received had considerable influence on the curative effect." One very serious obstacle to the treatment of internal tuberculosis by this method is the problem of the removal of the necrotic tuberculous tissue supposed to be thrown off as a result of the injection.

The practical fact remains, however, that an exceedingly small proportion of the cases subjected to the treatment have been improved; some have rapidly grown worse. Further disadvantages lie in the fact that the remedy is uncertain in its action, sometimes producing marked local and constitutional disturbance, and at other times having slight or no effect. Owing to the rapid dissemination which occurs in tuberculous affections at times, under any treatment, or without treatment at all, it is rather difficult to say on post-mortem evidence that an acute eruption of tubercles has been due to the tuberculin administered. In spite of this, however, Virchow, than whom none can speak with more authority, has noted fresh submiliary tubercles, particularly on the serous membranes, so frequently in autopsies on patients dying in the course of Koch's treatment, that the question of the causal relation of the tuberculin has forced itself upon him.

To speak briefly of the use of this remedy as a means

of determining when a tuberculous process has been brought to an end, I need but refer to the preceding paragraphs. To repeat, the reaction is uncertain, it does not cure in the vast majority of cases, so that its use for this purpose is rarely called for, and even if a tuberculous patient had progressed favorably under another treatment this test-injection might cause a rapid metastasis.

ADMINISTRATION.—Tuberculin is sent out in stoppered bottles, each containing 5 c.c. Its very great activity renders it necessary to dilute the fluid before administering it.

The diluting fluid is prepared as follows: A pint of distilled water is placed in a flask and boiled five minutes; forty-four grains of carbolic acid are then added and the liquid boiled one minute; cork and remove the flask from the fire. When cold, add to the solution, if necessary, enough boiled distilled water to make the whole measure one pint.

Having sterilized the necessary apparatus, the dilutions are made by attaching a pipette of 1 c.c. capacity to an ordinary half-ounce syringe by means of rubber tubing. With this, 0.5 c.c. of tuberculin is delivered into a 10 c.c. measure. The pipette is rinsed in the diluting fluid, the rinsings added to the lymph, and enough diluting fluid to make 5 c.c. Place in a sterile stoppered bottle, which may be labelled "Solution No. 1," or ten per cent. solution; 1 c.c. of this equals 0.1 c.c. of tuberculin, or 0.1 c.c. equals 0.01 c.c. of the lymph. Similarly, 0.5 c.c. of this mixture may be added to the diluting fluid, making as before 5 c.c.; label this "Solution No. 2," or one per cent. solution. One c.c. of this equals 0.01 c.c. of the pure lymph, or 0.1 c.c. equals 0.001 c.c. of the undiluted fluid. Again, 0.5 c.c. of the second solution is taken, and enough of the diluting fluid added to make 5 c.c. This is to be marked "Solution No. 3," or $\frac{1}{10}$ per cent. solution. One c.c. equals 0.001 c.c. of the original fluid, or 0.1 c.c. equals 0.0001 c.c. of tuberculin.

Distilled water, which has been boiled and allowed to cool, may be used instead of the one-half per cent. carbolic solution, provided the fluid is to be used at once; otherwise it is necessary to use the carbolic mixture, or to sterilize the solution by heat—in which latter case it will not remain stable long, but must be sterilized from day to day. This process tends to affect the strength of the tubercreulin, and therefore is not so desirable as the use of carbolic acid.

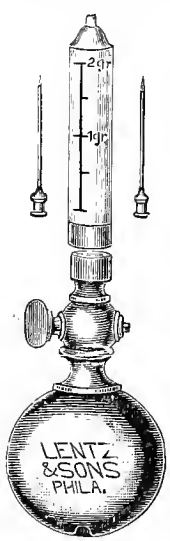

FIG. 651. — Koch's Modification of Pravaz's Syringe.

As the remedy has no effect when given by the stomach, it must be administered hypodermatically. Koch originally advised the back as the most suitable place for the injections, because by experience he had found the selection of this position to give less pain and inconvenience than other locations, and this recommendation has been almost universally adopted by those who have used the tuberculin. Between the shoulder-blades is a convenient point, or below them, in the region of the latissimus dorsi, on the side opposite to that on which the patient is in the habit of lying. The injections are preferably made with Koch's modification of Pravaz's syringe. It consists of a rubber ball, which is provided with a stop-cock, and which is adapted accurately to a graduated glass cylinder: to the opposite end of the latter the needle is adjusted.

The special advantages of this syringe are its simplicity and the ease with which it can be sterilized. To keep the syringe aseptic it should be cleansed before and after use. The glass cylinder may be rinsed in corrosive sublimate solution 1 to 2,000, or in carbolic solution 1 to 20, and finally in absolute alcohol. Needles should be cleansed and kept in 1 to 20 carbolic solution. Before using they should be rinsed in absolute alcohol. The skin of the patient at the point of injection, and the hands of the operator, should be well washed with soap and warm water, then with carbolic solution 1 to 40, and finally with absolute alcohol. By observing these precautions and by using a sterile fluid, but little if any inconvenience should result from the injection. In over one thousand inoculations, Koch did not have a single abscess.

After administering the remedy, the patient should be carefully watched, and the second dose withheld until all evidence of the previous reaction has subsided. After the injection, Koch advised that the patient go to bed; but unless the reaction is severe this does not seem essential.

DOSE.—In cases of lupus and the various forms of surgical tuberculosis, the initial dose should not exceed 0.01 c.c. of the original fluid (1 c.c. of the one per cent. solution). This amount may be more or less rapidly increased according to the severity of the reaction that follows.

In cases of pulmonary tuberculosis, the action of the remedy is much more pronounced. The maximum dose for the first administration should not exceed 0.001 or 0.002 c.c. These doses may be repeated daily if the previous reaction has subsided, and increased by 0.001 c.c. as the constitutional effects become slight. These small doses are particularly necessary if the patient is weak. In children, the commencing dose should be very small, 0.0001 to 0.0005 c.c., to be increased by 0.0001 c.c. according to the effect produced.

DANGERS.—It is of course impossible to say, in any case of acute dissemination of the tubercles, whether a given post-mortem appearance occurred in the natural course of the disease, or whether it was precipitated by the tuberculin. As before pointed out, however, Virchow has seen so frequently extensive fresh submiliary deposits, particularly on the serous membranes, in patients that have been under the treatment for some weeks, that it may very properly be questioned whether the remedy did not bear a causal relation to the metastasis. This view does not seem unreasonable when it is remembered, as pointed out by Koch, that the bacilli are not affected by the tuberculin, and in the separation of the necrotic area new avenues may be opened for the entrance of the bacilli into the circulation.

Cases of pulmonary hæmorrhage have been reported after injections in patients with tuberculosis of the lung. This may be brought about either by the intense congestion during the period of reaction, or later from the separation of the necrotic area involving the blood-vessel. The danger in tuberculous ulceration of the bowel is even greater. Here, likewise, hæmorrhage may result from the opening of a blood-vessel when the slough separates; or perforation with septic peritonitis may occur from the same cause. Meningitis has followed in the course of the treatment in a few instances, but as it occurs under all circumstances it is impossible to do more than hint at this possible sequel. Theoretically, the remedy would also be dangerous in cases of tuberculosis of the urinary organs, on account of the congestion and swelling which ensues, thereby causing obstruction or suppression. Facial palsy has been reported after the use of the remedy, and probably indicated tuberculous disease of the middle ear.

Too much attention cannot be paid to the diet of patients undergoing this treatment, particularly in the advanced cases, in order to avoid if possible perforation of ulcers in the bowel.

Jolly has reported three cases in which mental disturbance has followed the use of the lymph. In the first patient the injections had been administered for two weeks. There was considerable constitutional reaction, with high fever and delirium, which was followed by a psychosis lasting two weeks. This is the so-called fever psychosis. Following the administration of the remedy to a feeble-minded person in whom there was but mild febrile reaction, melancholia and hypochondriasis developed. In the third case delirium accompanied the fever and disappeared with the latter.

Post-mortem Changes.—Virchow has described the following post-mortem appearances in the lungs of patients suffering from pulmonary tuberculosis, who had been treated with tuberculin. The most distinctive alteration corresponds to the condition called caseous pneumonia; pleurisy, simple and tuberculous, frequently hæmorrhagic, and often bilateral, is met with. "Injection" pneumonia somewhat resembles catarrhal pneumonia, but the infiltration in the former is watery and turbid rather than gelatinous, as in the true catarrhal affection. He suggests for this coudition the name "turbid pneumonia."

Dr. Crooke found in the lung of a patient who had died in the course of Koch's treatment for pulmonary tuberculosis, after the third injection of 0.003 c.c., that there was surrounding the caseous foci an intense inflammatory zone of leucocytic infiltration, both into the alveoli and into the walls. In another case, in which death had followed the fourth injection, there were to be observed unmistakable evidences of coagulation necrosis.

Tuberculocidin or Alexin.—On account of certain disadvantages possessed by tuberculin, various observers have endeavored to isolate the remedial constituents of the remedy and to eliminate the uudesirable substances. Of the many modifications which have been subjected to experimentation, the only one that seems to deserve notice is tuberculocidin, which was first described by Dr. E. Klebs, of Zurich (*Deutsche medicinische Wochenschrift*, No. 45, 1891). It is prepared from the crude lymph by precipitating with one of the alkaloid reagents, as platinum chloride. The precipitate contains the noxious constituents, while the albumoses remain in solution. If so desired, they may be obtained in a pure state by precipitation with alcohol. Tuberculin yields about two and a half per cent. of tuberculocidin. As in the case of Koch's remedy, the tuberculocidin is tested on tubercular animals before being put upon the market, so that a certain standard is always maintained. According to Klebs, in non-tubercular animals his remedy causes no disturbance in the temperature nor depression of the heart. It is claimed that tuberculocidin is the secretion of the tubercle bacilli. This offers a possible explanation of the statement made by certain observers, that a few doses of TC (as Koch abbreviates tuberculocidin) cause the decomposition of the tubercle bacilli. The temperature reaction after injection of TC, as a rule, is very slight and lasts but a short time. Under the continued use of the drug the fever is said to disappear entirely, and it is even claimed that it possesses antipyretic properties.

It is advised to discontinue the use of the drug at intervals, since its uninterrupted administration might give rise to malaise and loss of weight. Tuberculocidin is said to render animals temporarily immune to tuberculosis. Klebs believes that the remedy is retained in the body, and that it acts directly on the bacilli as soon as they are introduced by inoculation. He has shown by experiments on animals, that fully developed tubercles are entirely rednced under the actiou of TC. As a result of his observations he concludes that two grammes of TC per thousand grammes of body-weight may be given in the course of three or four days without harm. It was found that injections of 0.1 gramme per five hundred grammes of body-weight, given successively for twenty-five days, was sufficient to cure animals which had previously been inoculated with tuberculous material, even after six weeks had elapsed since the inoculation. From this it is estimated that the amount per diem necessary to cure tuberculosis in man would be 1 to 1.2 c.c. for a person weighing fifty to sixty kilos. This dose may be increased to 2 c.c. daily with entire safety. Of 33 cases of tuberculosis submitted to this treatment by Klebs, 8 are reported as cured, and 21 improved; of 42 additional cases treated by others, 6 are reported cured, and 24 improved. There were two deaths during this treatment. Of the remaining cases, in some there was no change and in others a general improvement is recorded. It is stated that necrosis of the tissues and propagation of tubercle bacilli never occur during the treatment with TC. As a rule, it is not necessary that the patients should be confined to bed during the administration of the remedy.

In administering TC the hypodermic syringe of Overlach is recommended, observing the same antiseptic precautions as described under tuberculin. A series of injections is to be considered quite successful if the temperature remains between 36° and 37° C., without regard to decrease of the cough and of the amount of expectoration. Greater diurnal fluctuations of temperature indicate the necessity for an early repetition of the injection. Rises in temperature which cannot be accounted for otherwise, show that the morbid process is not quite suppressed. In his latest communication Klebs states that a rise in temperature is an indication for increasing the dose, and that the remedy does not cause fever, as was at first supposed.

The use of tuberculin and its modifications has been almost totally abandoned, as already stated. Isolated observers are still experimenting with the remedy here and there, but no constant results have been obtained that would warrant its general use. At the present time it would seem that the employment of this drug should be restricted to properly appointed hospitals, and under the direction of competent observers only.

Perhaps the greatest misfortune which has occurred in the history of this discovery is the enthusiasm which Koch's first announcement aroused. It can safely be said that the only motive which actuated the discoverer was to learn the true value of the remedy. The process of reasoning and the line of experimentation which resulted in the production of tuberculin is unparalleled in the history of medicine, so that if it is finally found to be without value, the discovery in this manner of a remedy which has so marked an affinity for tuberculous tissue, must ever remain a triumph to the author.

The following, taken from a letter written by Professor Guiteras (*University Medical Magazine*, vol. iii., 1891, p. 372), expresses a just appreciation of Koch's work:

"It was very evident that only one thing could produce the remarkable effects of this lymph, and that is the tubercle bacillus itself. To think of anything else producing such results, we would have been forced to build, upon new principles, an entirely new pathology.

"The statement made by Professor Koch is a model of simplicity and clearness. The directness of his line of investigation, from the first suggestive fact to the final conclusion, is an unsurpassed attainment of mental discipline. The triumph of the author is complete. He has discovered new facts, he has studied them thoroughly, and he now announces them with becoming modesty. If we remove from this discovery all possibility of success as a therapeutic agent, if we take away the wide-spread interest it has awakened, it still remains unequalled by any other discovery in the history of medicine. For Professor Robert Koch has given us the first clear insight into the functional pathology of the approaching epoch." *Alfred C. Wood.*

TUBERCULOSIS OF THE PERITONEUM, DIAGNOSIS AND TREATMENT OF. Among the intra-abdominal conditions that render a determination of their character doubtful or difficult, none equal tubercular lesions of the peritoneum or its contents. The cyst or papilloma, the fibroid or sarcoma, may turn out, under an exploratory operation, tuberculosis pure and simple, to the confusion of the most expert diagnostician. Of seventy recorded cases of laparotomy in tubercular disease of the peritoneum, or of the abdominal organs, forty of them were discovered as errors of diagnosis upon the operating-table, and nearly all were reported by distinguished men. This doubt and confusion attending tuberculosis of the peritoneum, from the surgeon's standpoint, will always give it intense interest independently of questions of pathology and treatment. Sick states that among 2,500 post-mortem sections made at the new General Hospital of Hamburg, but forty-six cases of tuberculosis of the peritoneum were noticed. This is a striking illustration of the infrequency of the disease, and why it may so unexpectedly reveal itself upon the operating-table to the confusion of the most expert diagnostician.

Our interest and knowledge concerning tuberculosis of this region is contemporaneous with the development of abdominal surgery. Previous to that a diagnosis was a post-mortem affair, except as the disease was found associated with advanced lesions of the lungs or other parts. It is doubtful if a diagnosis of tuberculosis can be made simply as a pathological condition; the diagnosis must be based upon the status of the lesion. The clinical features are thus constantly changing, each advancing phase, and each part of the abdominal contents successively invaded, modifying or offering a new group of symptoms. A case that at first presents itself as one of free ascites unassociated with any appreciable abdominal growth, may, on another examination a few months later, offer all of the physical signs of ovarian cyst; or while the fluid accumulation may remain free, irregular and nodular growths, giving what seem to be unmistakable signs of malignant tumors, may startle and confuse us at a later examination. An intelligent study of tubercular peritonitis, with a view to its diagnosis, calls for a division of the subject. Such a division would naturally fall into the following order: (*a*) Free ascites; (*b*) encysted ascites; (*c*) tuberculosis of the pelvic organs; and (*d*) tuberculosis of the abdominal organs.

(*a*) *Free Ascites.*—It may, in our present knowledge of the subject, be undertaking to prove too much, to claim that in a given case of free ascites we may be able to recognize it as the effusive stage of a peritonitis due to tuberculosis; but without asserting too much, it is a subject well worth looking into. In the first place, in such a condition have we really a peritonitis, as understood in the idiopathic sense of the word? No one claims that tuberculosis of the lungs is a pneumonia, although in some of its periods of development it offers symptoms closely related to that disease. If we examine the life-history of the bacillus, we shall see that inflammation is not the agency by which it works out the circle of its life and propagation. The tubercle is a stage of development only—the chrysalis, as it were, of a colony of bacilli lying dormant until ready to swarm forth and invade new territory. We know also that frequent instances occur in which this chrysalis never matures, and the bacillus remains dormant and at last becomes buried in a mass of plastic or fibrous exudate. The first means a destruction of adjacent tissue, the second a latent case. We know from clinical observation something about the manner in which this destruction is effected. In lung tuberculosis we do not observe the matured tubercle in the sputa, but the liberated bacillus. Histologically, it has been shown that liberation consists in a breaking down of the containing capsule, or in other words, of the tubercle itself. This process in the peritoneal cavity does not always lead to effusion, even when general, and when local, as in the inner genitals of women, great masses may form without a suspicion of an inflammatory process.

Effusion may begin without abdominal tenderness and without a febrile condition, and with the nutrition unaffected. Here is a condition that, if unexplained in some other way, ought to create a suspicion of tuberculosis. Another matter which has been quite generally overlooked, is the history of the habitual environment of the patient. The bacillus does not originate *de novo* in the peritoneal cavity, it migrates from without, or from some other part. Thus at the Woman's Hospital, a year ago, I removed the tubes by laparotomy for tuberculosis in the case of a woman who had lived with a husband affected with tubercular consumption, and who died within a few weeks after her return home. It is easy to get an explanation of the manner of infection here. This unfolds another fact worthy of attention. In our hypothetical case of free ascites, is the subject a woman? Now, pelvic invasion is common in women, rarely, if ever, met with in men. The reason is clear. Woman offers an open road to the migration of the bacillus through her genital track direct to the peritoneum. It is as open and direct as that of the bronchi to the lungs. This is why the history of the woman and her environment will throw light upon the diagnosis. My own experience of this disease does not embrace a very large number of cases, but it offers a group extremely valuable in this relation. In every case the woman gave a history of tuberculosis in her own family, or had lived and cohabited with a tubercular subject.

We frequently observe free ascites associated with pelvic tumors both large and small, but the gynecologist having established that fact, would not be justified in accepting it as a sufficient explanation. But if an evident salpingitis existed associated with a pelvic exudate and uterine fixation, it would be difficult to assign any reason other than tuberculosis for the ascites. Another condition, that ought to throw suspicion on the ascitic accumulation, would be its association with chronic adenitis of the cervical glands or indolent abscess of the part. This condition is called scrofula, but it is as much a tuberculosis as the abdominal scrofula of the old writers. A subnormal temperature that may exist for weeks or months at a time, has been found attending tuberculosis of the peritoneum. This is an important fact, and was not generally known until Dr. William Osler called attention to it in his exhaustive monograph. Pigmentation of the skin, especially of the face, has been repeatedly observed, simulating that of Addison's disease. Osler believes that the symptom may be present when the tubercles are confined to the peritoneum. Extreme tympanites is very often found, as one would reasonably expect from the impairment of the muscular tone of the intestines.

We must exclude diseases which may be attended with fluid accumulations within the peritoneum. The usual urinary examination would not exclude an implication of the kidneys, as the adrenals may be involved in the general invasion of the abdominal organs. The face is free from effusion, as are also the lower extremities. Effusion due to cardiac disease and to cirrhosis and cancer of the liver, would have to be eliminated from the problem, and if the patient had been under observation from an early period of the disease an effusion from such a source could be differentiated, but in the later stage this would be difficult. The peculiar character of the effusion would point to disease of the liver, which organ ought to receive the most careful scrutiny. We have to look to the lungs as organs which will give the strongest confirmation to the diagnosis of tuberculosis of the peritoneum, It is not known what proportion of cases show the coexistence of the two diseases at the early stage we are considering; but it is comparatively frequent, and if the diagnostic features already mentioned are present, the disease might safely be pronounced tuberculosis. In a study of the encysted form, as we shall presently see, coincident lung affection forms a most important guide to a knowledge of the peritoneal condition.

Lastly, the bacillus may be found in the effused fluid, and, when present, is a positive indication to the nature of the disease. But it is not always found. In a case of my own, in which an exploratory laparotomy was made, the fluid was carefully examined for bacilli, by an experienced microscopist, with negative results; the operation, however, revealed large masses, apparently having their origin in the tubes, rising out of the pelvis and extensively involving the omentum and intestines, the peritoneum throughout being covered with dark-colored tubercles of different sizes. The fluid was dark-brown, and in it were floating numerous flakes of lymph. I thought the failure to detect the bacillus in fluid of this character, with such extensive masses of the disease, must have been an error of observation, and I again had a more careful examination made, but with the same results. The bacillus has usually been sought for in the tubercle itself, and found in that situation. This method of diagnosis would imply at least an exploratory incision. Such an examination of the tubercles ought always to be made, for, as Spaeth has pointed out, there are numerous cases in which the suspected nodules have the appearance of tubercles, but which prove to be nodular forms of chronic peritonitis or lymphomatous masses. This observation has since been confirmed by several

observers. It is thus seen that our difficulties of diagnosis do not diminish even after an exploratory incision. This method of examination is too dangerous to undertake lightly in advanced stages of the disease. The case to which I have just referred terminated fatally on the third day, and I believe other surgeons have had a like experience. These advanced cases of general tubercular degeneration of the abdominal organs react in very much the same manner as do malignant cases after exploratory operations.

In a recent article by Dr. Edebohls, mention is made of "plaque-like, localized thickenings of the deeper portions of the abdominal parietes, perceptible to gentle touch." This condition was observed in the flat abdomen. It is a valuable sign if it can be detected, which I doubt; I have not noticed it in any case of my own. It is well worth bearing in mind. In cases without effusion Osler's observation, that the "association of a tubal tumor with an ill-defined, anomalous mass in the abdominal cavity," ought never to be lost sight of while endeavoring to make a diagnosis.

(*b*) *Encysted Ascites.*—In the diagnosis of encysted tubercular ascites, I cannot do better than to briefly review what I said some time ago upon this question in my paper, "Laparotomy as a Cure for Tuberculosis of the Peritoneum," which was published in the *American Journal of Obstetrics*, September, 1887. The patient was twenty-eight years old, married, and had one child, a year old. She had noticed a gradually advancing enlargement for two months. She was losing flesh and menstruation was very scanty. Fluctuation was marked but diffuse, extending in an evident wave over the abdomen when the patient was upon her back. In this position the abdomen was flat with bulging upon either flank, and with protrusion of the umbilicus. In this position, also, the area of percussion dulness corresponded to the extent of lateral fulness, while the umbilical region was clear—an evident intestinal note—down nearly to the pubes. On changing her position to the side, the upper flank became clear on percussion, while the region of dulness was transferred to the lower side on a line nearly to the level of the umbilicus and parallel to the body axis. On reversing the position, the regions of dulness and clearness changed sides. The examination of the pelvic organs gave negative results. The uterus approximated the normal in size and position; the organ was freely movable and was not affected by abdominal manipulation, except by the percussion wave which could be felt in the vaginal cul-de-sac. The region of the liver was free from tenderness and gave a normal outline on percussion. The temperature was normal, the appetite fair, there was no cough. She complained of indigestion and a tendency to looseness of the bowels with flatulency. The urine was stated by the patient to be normal in amount. The specific gravity was 1.019, acid and free from albumin. There was no œdema of the feet or eyelids. There was but one diagnosis to be made here, that of ascites; but there was no evident cause of the effusion. She was placed upon tonics and diuretics, and sent home. She was seen at intervals of two or three months. There was no change other than a slow increase of the ascites and loss of weight. In the following spring she had a troublesome cough which lasted five or six weeks, but abated under the use of simple remedies.

Nothing further was seen of the patient until late in the fall of the same year. A complete change was then observed in the condition of the abdomen. The outline had lost the character of a free fluid effusion, the flatness of the abdomen and the bulging of the flanks had disappeared, and the abdomen had become prominent and rounded. The area of percussion dulness had changed from the loins to the central region. By deep palpation in the right iliac space an irregular, hardened mass could be detected, and an induration of apparently the same character could be felt near the right hypochondriac region, having a right and left direction. The wave of fluctuation was limited to the line of dulness at the epigastrium and at the flanks. The uterus seemed free from any connection with the abdominal masses, and was in a fairly normal position. The umbilicus was still protuberant. There was no cough or hectic, and the temperature was about normal; she had wasted considerably, the face was pinched, and the expression such as is seen with ovarian cystoma, not like that observed in malignant disease of the pelvic or abdominal organs. The urine was free from albumin. The aspirator brought away about a quart of straw-colored fluid. Laparotomy showed how all this remarkable change came about. The peritoneum was of extraordinary thickness, the intestines lying behind the effusion were highly injected and matted together. The stomach and the transverse colon were united with the peritoneum and enclosed the effusion. All the parts were beset by thousands of tubercles, some white, some yellow, and of various sizes. The irregular masses were composed of the adherent and thickened organs. I was fortunate in being able to observe the case throughout its course, and in the light of a laparotomy to be able to trace each step in the development. One might hunt in vain to find a parallel case due to causes other than tuberculosis, or one in which the successive stages in the evolution of the case were brought out in such clear relief. Here we had the heart, lungs, liver, and kidneys in a normal condition and without any history of previous peritonitis, but associated with an abundant free effusion into the peritoneal cavity. On examination of the pelvis, the organs there were found to be healthy, without tenderness, nodes, or tumors. All ordinary and usual causes of ascites were therefore eliminated in this case. Speaking with a due regard for the anomalism of disease, we had only peritonitis left to explain the phenomena; but the absence of any of the necessary symptoms of this disease showed that it could be of no ordinary form, while the freedom of the lungs from any indication of tuberculosis simply rendered uncertain what, with this indication, would have been a fairly clear case of the abdominal form of the disease. Nothing was added to this history for months except meteorism and a pulmonary irritation which was self-limited, and a gradual wasting of the body. Then, on examination, a state of affairs presented itself which could reasonably characterize but one thing—the free ascites had become encysted without a cyst to enclose the contents. In the whole range of pelvic and abdominal disease, under the conditions named, I know of none that offers this peculiar anomaly except tuberculosis of the peritoneum. This disease has two leading traits: one is plastic exudation, and the second is effusion. The first is always present, the second is absent in many cases, but when it characterizes a case it is the initial symptom, and is sure to become incarcerated by the adherent organs. Our case further demonstrates that miliary tuberculosis of the peritoneum may antedate the development of tubercular nodes and tumors upon the ovaries and tubes, and that it persists to nearly a fatal stage without these parts becoming secondarily involved.

(*c*) *Tuberculosis of the Pelvic Organs.*—We may have pelvic tubercular disease without ascites. A case of a young girl, seventeen years of age, upon whom my colleague in the Woman's and Children's Hospital, Dr. A. B. Breese, made a laparotomy, offers a very interesting proof of this. The pelvis was occupied by distinct but not sharply defined masses in the situation of the broad ligament. The girl was extremely delicate, with advancing emaciation and anæmia. Menstruation had never been regularly established. The outlook was so very unpromising that I concurred with Dr. Breese in the necessity for laparotomy. The tubes and ovaries were mingled in indistinguishable, highly vascular masses, which were enucleated with difficulty and at the expense of a copious hæmorrhage; but a very unusual feature of the case was a rounded fleshy mass, nearly an inch in diameter, which just above the pubes stretched across the pelvis from side to side. It was adherent at both ends, very vascular, and made up of extremely friable tissue that a ligature would cut. A careful examination showed that it was composed of the lower border of the omentum. The operator now did a thing which he has never had cause to regret, but which my laparotomy friends,

who clean anything and everything out of the female pelvis with such praiseworthy industry, would surely condemn—he let it alone. The patient made a rapid recovery, and now, two years after, is a strong, hearty girl. An examination showed that it was a case of tubercular degeneration of the parts. There was also a consumptive taint in the family. What became of our omental tumor? We simply know that it never afterward gave any trouble.

There are several diseases that may be confounded with tubercular peritonitis when the onset is sudden. For example, it has been confounded with hernia. Such a case has been reported by Thomann in which an operation was actually made. Typhoid fever has been repeatedly confounded with it; but usually the mistake is made of regarding it as a simple acute peritonitis. It is in these acute cases that a moderate amount of ascites may be met with that rapidly assumes the encysted form; or it may present this feature from the beginning, owing to the extensive adhesions that are formed between the peritoneum and the abdominal organs previous to the effusion. Very extensive accumulations are not common. Biat, quoted by Osler, states that in eighty-one cases, thirteen only were attended by extensive ascites. A moderate ascites may thus be assigned some value in differential diagnosis. This encysted form does not always present symmetrical or uniform outlines. In a case of which I saw the post-mortem, the omentum formed a flattened tumor, which confined the fluid to one side, giving a very distorted appearance to the abdominal outline. In life the fingers could be inserted under the edge of the advancing growth, which began above and to the left, and progressed obliquely downward and to the right. It was diagnosticated as an omental tumor, but tuberculosis was not thought of until at the post-mortem. According to Fagge, an obscured intestinal note may be obtained by firm percussion over the mass, especially when overlying a distended colon.

Osler divides these sacculated exudations into three abdominal zones. In the upper, which includes the liver, stomach, and spleen, confined accumulations of fluid are common, which may belong to the gall-bladder, stomach, or spleen. In the middle zone, from the transverse meso-colon to the false ribs, and which includes the omentum and intestines, sacculation is much more common. Ovarian tumor, if an error is made, is the usual diagnosis. The ovarian growth may generally be traced from the pelvis upward, while the fluid exudate of tubercular peritonitis begins in the middle zone. As already stated, these exudations of tuberculosis may not be in the middle line, but confined to one side or to a limited area in the centre. In these cases it would not be easy to confound them with ovarian tumor. Diagnosis becomes still more difficult when the coils of intestines are thickened and adherent, giving most distinctly the sensation of solid tumors. In tuberculosis these are more frequently situated in the cæcal region. In the lower zone the disease may be confined to the parietal peritoneum, which has formed adhesions to coils of intestines, and thus confines the fluid to the pelvic cavity. In such a case, the solid or nodular enclosing wall here and there may possibly give an obscured intestinal percussion note, which would serve to give a hint of its origin. The pelvis, however, offers conditions for tubercular disease radically different from those observed in the abdominal cavity proper. In the first place, tuberculosis of the tubes and ovaries is generally the primary condition, or at least sufficiently common to account for the excess in frequency of tubercular peritonitis in women over men. It is the initial lesion, the point at which the invading bacillus halts, and from which it invades remoter regions. As already referred to in speaking of free ascites, if encysted ascites follows disease of the tubes we have a right to suspect a tubercular origin. If nodes or distinct masses are observed in the abdomen, following upon trouble referable to the region of the pelvis, without the usual history of acute salpingitis or pelvic peritonitis, tuberculosis will naturally first suggest itself as an explanation.

There are intercurrent conditions that may afford some aid in determining the character of the abdominal disease. Dr. Howard, in his paper in the Gynecological Society's Transactions for 1885, states that a number of observers have noticed a red blush on the surface of the central portion of the abdomen. This is probably a late sign in advanced tuberculosis of the peritoneum. Effusions in the pleura attending abdominal tumors have been very generally regarded as signs of malignancy. Mr. Tait positively expressed that opinion, and has only recently met with a case in which this rule was at fault. It has, however, been repeatedly noticed as attending tubercular peritonitis, and has been usually found to be coincident with the effusion stage of the peritonitis; associated, however, so far as I am familiar with the reported cases, with an extension of the tubercular disease to the lungs. It is well to note, then, the marked difference between the pleural effusion of malignant abdominal disease (unassociated with lung complication) and tubercular peritonitis associated with disease of the lungs. Further, the implication of the lungs without effusion has even a greater value as defining the abdominal disease, as it is more frequently met with—so often, in fact, in advanced stages of abdominal tuberculosis, that its absence would tend to throw doubt upon that theory of the condition. An adenitis of the supra-clavicular glands has been observed in the disease. I have seen this complication but once, and others may also have noticed the same, but it is not referred to in the literature of the subject. But as these glands very early become involved in many forms of abdominal tumors, this symptom could not be given any independent value in the diagnosis, its real place being but one in a group of differential signs. A pigmentation of the skin, especially of the face, has been given special importance to by De Mussy as significant of tuberculosis of the peritoneum. Osler, who makes the reference, states that Sir William Jenner, in a lecture, pointed out that this skin discoloration, as marked as in Addison's disease, attended a case of abdominal tuberculosis. In a case of like character, reported by Boulland, the supra-renal capsules were involved.

The treatment of tubercular peritonitis has in recent years received marked attention. This is due to the cures which have followed laparotomy. That such is the case may be now considered a matter of accumulated experience. Many abdominal surgeons have now independently observed that cases of tuberculosis of the peritoneum and of the abdominal viscera appear to undergo a remarkable amendment, or apparent cure, directly after the performance of laparotomy. This has been observed so frequently as to justify the opinion that it is a possible sequence. Why there should be an arrest of progressive tubercular development after laparotomy, it is difficult to say. We know too little about the tubercular process, to begin with, to predicate upon it any well-defined explanation; and, in the next place, there is a total lack of precision in the method. I said, as long ago as 1887, that there was no instance known of a laparotomy having been performed for tuberculosis; we simply learned the favorable results of the operation, mainly as the outcome of errors of diagnosis, as Hegar says. From what I have observed of its literature since that date, I have no reason to change my opinion. These cases are to-day more frequently revealed as a surprise upon the operating-table than as a condition clearly recognized at the bedside.

Concerning laparotomy itself there prevails the same confusion. At the first meeting of the German Gynecological Society, in 1886, and to which meeting we are mainly indebted for the general attention given to this interesting matter, the subject came up in an irregular way during the discussion of a paper by Elischer on the use of iodoform in the toilet of severe laparotomies. Dr. Frommel headed the diversion from the main topic of the paper, by stating that he had used the drug in two cases of tubercular peritonitis, and in another case of ovarian tumor with ascites and small papillæ all over the peritoneum. Hirschberg had cured peritonitis with tubercular nodules by corrosive sublimate; hence iodoform

was unnecessary. Dr. Meinert agreed with the last speaker so far as iodoform was concerned, but threw doubt upon the sublimate, as a like result may be obtained by incision and tapping. Dr. Olshausen had seen it cured by incision, but also stated, what we all know, that it may get well of itself, or remain stationary for years. Dr. Saexinger gave curative value to laparotomy, while Dr. Battlehner had seen the same results follow tapping. Hegar, in an exhaustive monograph, confined mainly to genital tuberculosis in women, published in the same year, gave the matter its definite place in literature. He reports two cases that were either cured or rendered stationary by laparotomy, and another case of apparent arrest in which nothing was done. Sir Spencer Wells, in 1862, was one of the first to whom this experience came, or at least he was the first to place his experience upon record. König reports a case of seeming cure, after the use of iodoform in the toilet of the peritoneum. Neuman reported two cases. Poten gave the report of a case operated upon by Hartwig, of Hanover, and which seems to be, from the description, identical with my own. Lindfors records a case of like character. Mundé has had three cases. Kelly reports upon four, each operation gaining but temporary success. Homans reports four cases, one being followed by apparent cure. Gardner, of Montreal, reported by Osler, has had two cures; Wilson, of Baltimore, one in which the patient lived for six months after the operation; Dudley, of Chicago, one case with death in four years. Osler has collected four cases from Spaeth. One died after operation; one in three months from acute phthisis; the third by an advance of the disease; and a fourth was in a fair way to die from the same cause. Shoemaker reports a case of recovery; Schmidt also a complete recovery, and one case followed by death five months later. Imlach reports five cases all apparently cured. Goodell reports four cases, with cures so far as he knows. In addition to the above collected by Osler, we have to add the seventy-one analyzed by Maurange, which completes the record up to 1889. This is a total of ninety-seven cases. Of these nine proved fatal after operation, fourteen died from generalization of the disease, twenty-nine recovered, sixteen survived six months, twenty-seven were alive at the expiration of a year, one four years, and one—my own case—six years afterward.

König has brought the statistics down to 1890 by the tabulation of 131 cases, being an addition of 34 new cases. Of these 89 were cured, and 23 greatly improved. Among those classified as cured, 30 gave sign of a renewal of the disease several years afterward.

Why laparotomy or drainage of the abdominal cavity should cause retrograde changes, if I may use that term, in the tubercular masses, has had some light recently thrown upon it by a case reported by Osler. Laparotomy was made upon a young woman for a doubtful tumor. It proved to be one of a tubercular nature, with effusion. She recovered with greatly improved health, and resumed her occupation. About six months later she was readmitted with pneumonia and died. The autopsy showed the changes that had occurred in the tubercles after operation. There was general pigmentation of the tubercular nodules. The "surface surrounding them was thickened and puckered as though from slight cicatricial formation. Microscopical examination showed that the tubercles in the peritoneum were composed of numbers of submiliary nodules, very fibrous, containing few cells in a firm tissue. In the middle of the masses, giant cells with several nuclei and fatty granules. No caseation in the nodules. Tubercle bacilli very abundant." In a very remarkable manner this appearance corresponds with the condition noticed in the post-mortem room. Dr. Henry P. Loomis, in a very able paper on the arrest or cure of phthisis, based upon the reports of 1,146 examinations made at the dead-house of Bellevue Hospital, gives us this valuable piece of evidence:

"There was a group of cases in which the pleura gave the same cicatricial puckering over masses enclosed in dense bands of new connective tissue. Another group, in which the lungs showed extensive fibrous tissue changes, the same character of pigmentation and the same giant-cell formation mingled with tubercles. It appears reasonable from the coincidences noted here that laparotomy merely places the surfaces in a condition favorable to spontaneous cure. Another condition has been noted as following laparotomy, namely, the formation of hard calcareous masses about a tubercle, in which state it remains indefinitely without change. Thus three conditions attending the so-called spontaneous cure may be noted: Thickening and contracting of the peritoneal surfaces, fibrous encapsulation, and calcareous formation."

It may be useful to review briefly the forms of tuberculosis of the peritoneum in which laparotomy may be expected to give favorable results. Kaulich, in an elaborate study of the disease, divides it into three groups. The first we may term the acute form, which advances by a series of attacks with pyrexia and intervening lulls, until the entire abdomen has been involved, without effusion, but with retraction of the abdominal walls. There is no record of the surgical treatment of this group, nor would it naturally fall under the observation of the laparotomist. The second group is characterized by an insidious invasion without pyrexia, but with ascites as a leading and early trait. In this class also we get the apparent spontaneous cures, for Kaulich's third group is composed of the second, which affords the phenomenon of decrease of effusion with general improvement. If cases belonging to this second group can be brought under treatment before the secondary lung invasion, and the disease thus be attacked midway in its advance from the genitalia to the respiratory organs, we have an ideally typical case for laparotomy. There can be little doubt that the removal of the effusion is the essential point. Distention by the accumulation, aside from the irritating qualities of its constituents, may act in a two-fold way to intensify the morbid process—mechanically, by pressure, and by affording a medium for the distribution of the bacillus. Braxton Hicks has given a very clear exposition of the intra-abdominal conditions associated with this state of tension, from which the inference is logical that the evacuation of the fluid is an effectual curative measure. Muret, quoted by White, states the fact that all the methods attended with success in the treatment of ascites have tended to produce a diminution of the intra-abdominal tension. Among these measures he includes the use of purgatives. Dr. J. W. White, in a unique paper on the "Supposed Curative Effect of Operations per se," has thrown much light upon this special subject while treating of this interesting matter generally. Analogous cases, quoted from widely different sources, prove the remedial effect of simply evacuating the fluid. If this be true, we see why tapping, or purgatives, equally with other methods, act as a cure; and if true, drainage through a large opening and a thorough toilet of the cavity must be the better way. There is another reason why laparotomy is better than drainage, which is forcibly stated by Tait. He says that a marked physiological alteration is induced by opening the abdominal cavity, indicated by a most distressing thirst, whichlasts for days—a symptom with which every laparotomist is familiar, and which is never observed of a like degree after any other operation. It can be readily seen how such a rapid diversion of fluids from the direction of the peritoneum must greatly modify the nutrition of the tubercles. In this way caseation, which may be regarded as an evolution of the tubercle to completion, is arrested. The irritated peritoneum is given a rest, and there is then established a process that belongs *per se* to tuberculosis, namely, a thickening and induration of the surfaces—the erection of a fibrous envelope about the tubercles, and a substitution of calcareous masses, which are indefinitely unalterable, in the place of the latter.

Helmrich, in a thesis, states that 65 communications are to be found in literature of the employment of Koch's tuberculin in the treatment of tuberculosis of the peritoneum. In one case of a girl of sixteen years, at the Gynecological Clinic at Basil, sixteen injections of 0.005 of tuberculin were made in the period of three

months. She died in about a year with pulmonary complications. In another case the remedy was employed after a laparotomy had been performed by Fehling. In a period of one month and a half twelve injections were made. The patient became healthy and able to work. The author concludes that from our present experience other means, such as medication, diet, and laparotomy, must be resorted to in connection with the treatment in order to get results from this agent, but that nevertheless it calls for a more extended experience.

While the changes which follow the employment of tuberculin are the same as those noticed in cases of spontaneous cure, changes still more striking have been observed after laparotomy. The tubercular nodules have entirely disappeared. Cases of this character have been reported by Hirschberg, Kuemmel, and Ahlfeld. And, lastly, it has been suggested that the cure due to tapping or laparotomy is the result of removing the ptomaïnes which may be present in the ascites, thus relieving the constitutional symptoms and permitting a renewal of nutrition. The conclusion is warranted that laparotomy and drainage constitute a method of treatment of tubercular peritonitis that is now placed upon a sound basis of experience in all cases of general tuberculosis of the peritoneum attended with ascites. We may, however, reach further results with surgical treatment in cases other than those thus defined. Nodular masses may develop on the tubes and ovaries and consolidate within the folds of the broad ligaments into fixed and irregular tumors, or the tubes and broad ligaments may form elongated, round, or uneven masses, but without the even and circumscribed tumor of a pyosalpinx. Another form of pelvic infection is that where the broad ligaments, ovaries, and tubes are consolidated into one mass in connection with a wide extension of miliary tubercular peritonitis. Here Hegar, except in cases in which other and vital organs are involved, would advise salpingotomy. The uterus must be dealt with separately per vaginam with the curette, or by means of caustics and iodoform, although Hegar treated one extra-peritoneally. The treatment by laparotomy offers some special difficulties not met with in pyosalpinx. The extirpation of the tubes is difficult, owing to vascular and close adhesions, and oftentimes to the doubtful safety afforded by ligatures in the friable tissues. The tubes are involved in the posterior folds of the broad ligaments, and Hegar cautions against breaking through to reach them, as it might possibly result in irrepressible hæmorrhage. Of course, such extensive breaking down of vascular adhesions requires drainage in the after-treatment. It is doubtful if, in such cases, salpingotomy will meet with general favor. Hegar's results are none too favorable to warrant such severe measures in search of a problematical cure. He had one direct death; the third case, as well as the fourth and fifth, rapidly developed secondary lung infection. I believe that in cases which present such extensive breaking down of adhesions a more conservative operation would give better results; that laparotomy, a thorough washing of the pelvic cavity with drainage, leaving the mass otherwise undisturbed, would, in the light of our present experience concerning the curative effect of laparotomy *per se*, possibly result in cure or arrest of the disease. The case of Dr. Breese, already mentioned, demonstrates the fact that the removal of all the tubercular masses in sight is not necessary in order to reach a cure.

A few words in conclusion as to how far our judgment ought to be modified by the likelihood of spontaneous cure. The statistical data upon this point are very meagre. There are no carefully recorded observations in the *post-mortem* room that correspond with those made by Loomis upon the lungs and published in the *Medical Record*. The post-mortem evidences of spontaneous cure after tuberculosis of the peritoneum would mainly resemble those described by him, namely, pigmentation and fibrosis. There is a very general agreement concerning the group of cases in which a natural cure may be expected as a possibility, and this is also the form of the disease in which laparotomy has given so-called curative results. The second group of Kaulich is defined by an insidious invasion without pyrexia, and with ascites as a leading and early trait. The third group of this author is simply the second exhibiting the phenomenon of spontaneous amendment in active operation. Another condition essential to this termination is that the lesion be confined to the peritoneum, without an active tendency to involve the lungs or pleura.

The lungs appear to be the region in which the life-history of the bacillus attains its perfect fulfilment. Here it multiplies with the greatest activity, and as a result produces its most destructive effects upon life and tissue. In other parts its course is more prolonged and its spread hampered by the resistance of normal tissue. In the latter the tendency to incapsulation and innocuous latency is, as a natural result, greater. This tendency may be assumed naturally to be intensified in proportion to the inherent disposition of the surrounding healthy tissues to limit the extension of the disease. In the lungs, in a general way, we may say that this normal environment favors rather than retards the extension of the invasion. If we refer again to the researches of Loomis we have the logical inference before us that the ratio which he observed of spontaneous cicatrization in the lungs, may be assumed to be true of the peritoneum plus the enhanced tendency of the latter part to limit the extension of the disease. Tuberculosis being a disease of exhaustion with pyrexia, the probability of spontaneous cure must largely depend upon the extent of invasion. It is well-known that the extension of the disease from the peritoneum to the lungs is almost inevitably fatal.

In the present state of our knowledge on this subject I may state that we have reasonable grounds to expect a spontaneous cure in the second group of Kaulich, namely, where the disease is characterized by an insidious invasion, slow and even advance, without, or with only occasional pyrexia, and with ascites as an early and a leading trait; when the disease shows no tendency to involve the lungs or pleura and the subject is a woman at or past middle life.

Osler has well expressed the conditions of spontaneous cure, and as it is not wholly in accord with the above expressed conclusions of my own, it is proper to give space to an author so well worthy of respect. "There is," he says, "no inherent improbability why tuberculosis of the peritoneum should not undergo involution as tubercles do elsewhere. Anatomically the peritoneal growth bears in its evolution a close analogy to the pulmonary, and this is further borne out by the retrograde changes through which it passes. Just as the aggregations of miliary nodules in the lung may undergo the changes which we speak of as healing, becoming hard and fibroid, so in the peritoneum the tubercle tends in many cases to become sclerotic and passes into a condition in which it is practically harmless. The beneficial result is more likely to be seen in cases in which, from the outset, the process is subacute and not associated with much exudation; but there are cases on record in which recovery has followed even after extensive effusion." Concerning the concluding clause in the last sentence, it may be said that effusion is a safeguard against damage to the viscera through adhesions, by keeping them separated. Adhesions may greatly favor the spread of the disease, and also, by the resulting impaired function of matted intestines, interfere with that degree of nutrition which forms so important an element in the self-limitation of the disease. Without effusion the disease assumes the form of the first group of Kaulich, in which there is retraction of the abdominal walls due to adhesions, and which of themselves are active factors in the fatal result. In cases in which laparotomy has been performed, ascites was the surgical motive for the operation, whether the diagnosis was an error or not; and in these cases, and for this very reason, surgery has given its best results. There is no record of laparotomy having been made upon the retracted abdomen for tuberculosis; so unfortunately from these data the opposite contention cannot be maintained.

The word cure is used only in the sense of a limitation of the invasion and a metamorphosis of the tuberculous

groups into new-formed products by incapsulation, calcification, with pigmentation. Caseous degeneration of the tuberculous nodules, while it has been observed to afford a more or less prolonged period of latency, can hardly be regarded as anything more than a condition favoring fibrosis, calcification, or incapsulation, and, contrary to some authors, in no way a condition possessing any power of its own to favor a spontaneous cure.

TUBERCULOSIS, SURGICAL. MODERN METHODS OF TREATMENT.—The treatment of tuberculous affections forms a large part of the surgeon's work. Until recently these conditions have been considered as a manifestation of scrofula, or of a strumous diathesis, and in their treatment the custom of applying local remedies, with or without rest, and the administration of general tonics was universal. These measures failing, as they commonly did, extensive operations became necessary to eradicate the disease. With the rapid development of modern surgery there has been a tendency to operate early in these cases and consequently spare the patient such radical measures. The best illustration of this is seen in the case of tuberculous inflammation of the knee-joint. Until a very recent period no operation short of excision was performed for the relief of this condition, and amputation was often resorted to. The most favorable result, therefore, was recovery with a short limb and with bony anchylosis at the seat of excision. Now, surgeons operating early, are able to attack the disease by opening the joint and removing the affected areas, either with the knife or curette, thus substituting arthrectomy for the more grave operation of excision or amputation. After arthrectomy in a favorable case the patient recovers with a good range of motion in the joint, and if anchylosis does occur there is at least no shortening of the limb. Since the pathology of tubercle is now understood, and its curability in certain cases has been demonstrated, there has been a tendency to attack the disease still earlier.

Recently, local tuberculous affections have been treated by the injection of a large variety of substances by different surgeons, in the hope that the disease could thus be arrested. An attempt is thus made to cure these troubles without operation, and also to successfully treat those cases that are not accessible to surgical interference. The literature of the subject is already voluminous, the reports of many of the observers show a very fair degree of success attending this treatment and certainly warrant a more extended trial. The different substances used have been largely those supposed to be destructive to the tubercle bacillus. The most important of these are arsenious acid, balsam of Peru, camphorated naphthol, carbolic acid, creasote, iodine, iodoform, zinc chloride, and tuberculin. At the present time we may dismiss all but the three last mentioned. These have been subjected to extended trials, while the others have been more or less completely abandoned after the initial observations. It is not probable that any of these methods will supplant surgical measures to any great extent, but it is probable that the best results will follow a well directed combination of the two. Of all the drugs employed so far, iodoform pre-eminently takes the first place.

IODOFORM.—The question of the germicidal action of iodoform has been the subject of much discussion. Mosetig von Moorhof, Bruns, Verneuil, and others attribute a positive anti-tubercular effect to iodoform. König believes that tuberculosis cannot develop in rapidly organizing and contracting scar-tissue. Brodnitz states that the results of the operative treatment of bone and joint tuberculosis have considerably improved since the introduction of the use of iodoform. Billroth speaks highly of iodoform as an anti-tuberculous material. He says, in summing up his experience, "The results have surpassed my boldest expectations." Von Bergmann likewise commends the injections of iodoform-glycerine in local tuberculosis, and confirms the opinion expressed by König in which early resections were condemned. Küster speaks highly of this treatment, and it is also commended by Koch (Dorpat). Verneuil believes iodoform is a specific against the tubercle bacillus. Von Büngner says: "No one can now deny that iodoform has an anti-tuberculous effect, and many cases of the disease are thus cured."

The exact mode of action in these cases is still uncertain, but the weight of evidence seems to rest with those who hold that iodoform does not possess any positive germicidal action; it is probable, however, that its decomposition-products are somewhat active in this regard. In spite of this fact surgeons have for many years placed much confidence in the beneficial effect of iodoform in tuberculous and other specific processes. It was probably this knowledge that led Billroth and Mikulicz in 1881 to employ injections of iodoform in surgical tuberculous affections. Since this time the method has been extensively employed by German and French surgeons, but particularly by the former. The beneficial effect of these injections is variously explained by different authors as dependent upon a bacillicidal influence and upon a stimulating effect upon the surrounding healthy tissues by which the diseased process is limited and eventually absorbed. Conservative writers are inclined to attach some importance to each of these theories. The particular combination of iodoform and its preparation for use is a matter of the greatest importance. Iodoform-ether, which has been largely employed in France by Verneuil, is objectionable for the reasons that it is irritating, it is much more liable to cause iodoform poisoning, and the results are not so good as where other combinations are used. Opinion is divided between the mixtures made with olive oil and with glycerine. Of the two the latter is perhaps more generally preferred. In either case the strength is the same, ten per cent. of iodoform. The greatest care is requisite in the sterilization of the mixture, as the presence of iodoform does not insure against miero-organisms. The term "emulsion," which was originally applied to the combination with gum arabic, and retained for the mixtures made with oil and with glycerine, is still largely used, but the physical condition which exists in the combination with the two latter vehicles is much more correctly expressed by the word "mixture."

Stubenrauch has referred to reactions of a threatening character following injections of iodoform, such as great swelling, severe pain, iodoform exanthemata, etc. Garré believes these untoward effects to have been due to the use of a mixture which was not sterile. He states, that in hundreds of injections in the Tübingen clinic he had never observed such results.

Iodoform intoxication is reported to have followed the injections in a few instances, but this will be a most exceptional occurrence if the iodoform-oil or iodoform-glycerine mixtures are used. As much as a fluid ounce, or two, may with safety be employed.

De Vos recommends the following method for the sterilization of iodoform-oil: Into clean, black glass bottles of proper size ten grammes of iodoform are placed and the bottles filled with a solution of corrosive sublimate, 1 to 1,000, well shaken and allowed to stand four days. The sublimate solution is then decanted and the iodoform repeatedly washed with freshly distilled or boiled water. To this aseptic iodoform is now added ninety grammes of olive oil, previously boiled ten minutes and cooled to 30° C. and the mixture repeatedly shaken. Brodnitz recommends the sterilization of iodoform-glycerine as adopted by Levy. Into common medicine-bottles of twenty grammes capacity are placed two grammes of iodoform and eighteen grammes of glycerine; corks are tightly inserted and tied. The bottles are then immersed in salt water and subjected to a temperature of 110° C. for from two to three hours. By means of tongs the bottles are removed from the hot-water bath and the necks quickly dipped in melted paraffine to seal the corks and prevent the entrance of air. Before use the bottles are washed with sublimate solution and the contents are poured into small dishes which have also been so sterilized. In this way a fresh bottle can be used for each operation. To prevent decomposition the bottle should be kept from exposure to light. A brown-red coloration of the glycerine indicates the liberation of iodine; when the mixture has assumed this condition it should be rejected. Böhni prefers a solution of iodoform to a mixture, and therefore uses oil of sweet almonds as a vehicle. This oil will dissolve as much as five per cent. of iodoform. Personally, I prefer a mixture containing ten per cent. of iodoform with seventy-five per cent. of glycerine, and twenty-five per cent. of water. This preparation, being less viscid than if pure glycerine is used, is more convenient to manipulate in the syringe, it penetrates the ramifications of sinuses and joints, or other cavities, better, and I believe causes less local reaction.

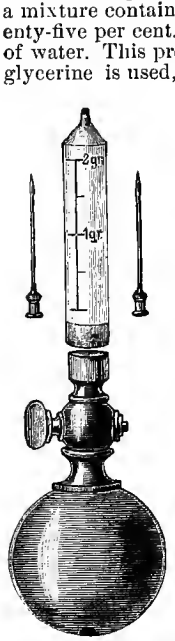

FIG. 652. — Pravaz's Syringe (Koch's) Suitable for Parenchymatous Injections in Tuberculous Diseases.

The iodoform for this purpose should be in an impalpable powder rather than in the coarse particles in which condition it is so often met with. When made by the usual process it has a crystalline character, which is altered by powdering, but almost always a number of coarse particles are to be found in the powder. That made by electrolysis is entirely free from this objection and is therefore to be recommended. A very satisfactory product is made by E. Schering, of Berlin, Germany.

Application.—The method of using the different combinations referred to is the same. Undoubtedly the best results will be obtained by the most careful application of modern aseptic principles in making these injections. To secure this end, in addition to the careful preparation of the mixture as described above, the syringe, the skin of the patient, the hands of the surgeon, and all utensils coming directly in contact with the fluid should be thoroughly cleansed. Parenchymatous injections are most conveniently made with the Pravaz syringe. In injecting large cavities a syringe of proper size, with a nozzle to fit the cannula used in aspirating, should be employed. The injections are to be repeated every eight days to two or three weeks, according to the degree of reaction resulting. The application of this treatment may be best detailed under the following special localizations of the disease:

TUBERCULOUS LYMPH-GLANDS.—If they have not yet broken down, injections into and about the affected glands should be practised about every eighth day. A single puncture through the skin should be made, but by partially withdrawing the needle five to ten drops of the mixture may be inserted at several points. If softening has already occurred a quantity of the mixture should be deposited in the degenerated area, and injections about the circumference of the disease also made. If the vitality of the skin overlying the abscess is impaired, the needle should be entered through healthy skin at some contiguous point. It is well always to draw the skin to one side before making the puncture, so that on withdrawing the needle the tract becomes subcutaneous. When the glands have become the seat of a mixed infection, suppuration will not be prevented by the use of the injection, and they should be subjected to one of the usual surgical procedures—incision, excision, or erasion—after which the iodoform mixture may be used as a dressing and for parenchymatous injection, in the surrounding infiltrated area. This treatment has not been used extensively enough as yet in glandular tuberculosis to determine its exact value, but it does not seem likely to supplant, but rather to be an adjunct to, other surgical measures. If the glands are in a position in which removal is possible, the treatment will be much shortened by resorting to this measure.

SINUSES.—A number of instances have been reported in which tuberculous tracts have closed under the influence of the iodoform treatment. It is necessary to inject the mixture in the walls of the sinus, and the cavities may be filled with gauze saturated with the same substance.

COLD ABSCESSES. — Continental surgeons have employed iodoform in cold abscesses very extensively in recent years. Billroth proceeds as follows: Under aseptic precautions the abscess is evacuated, the cavity thoroughly flushed with a solution of corrosive sublimate, 1 to 3,000, the iodoform mixture introduced, and the wound closed with sutures. When necessary this is repeated in four or six weeks; the majority of cases requiring the second, third, or even more treatments. It is reported that fifty per cent. of the cases were thus cured.

Bruns reports one hundred cases of cold abscess connected with the vertebral column and sternum, subjected to the iodoform treatment, with eighty cures. Brodnitz reports twenty cases of cold abscess treated by this method. Of these nine were definitely cured; eight had fistulæ remaining; and three had not been heard from. Of the cured cases, three were treated by puncture and injection; four by packing after incision; one with incision and primary suture; and one by incision with secondary suture. Recent medical literature has contained many reports from representative surgeons similar to those just given. The conclusion seems justifiable, therefore, that in iodoform we have a valuable addition to our resources in the management of tuberculous abscesses.

The method of its use has been already indicated. The strictest asepsis is imperative. This having been attended to, the abscess may be aspirated and the iodoform mixture injected, or the fluid may be evacuated by incision, followed by primary suture and the introduction of the remedy, or the cavity may be packed with iodoform gauze and secondary sutures employed. The particular method adopted must be left to the special indications of the case and the preference of the surgeon. In those cases in which incision is employed, the walls of the cavity should be gently curetted or roughly brushed over with a sponge, in order to remove as much as possible of the unhealthy membrane. If the abscess is aspirated the cavity should be irrigated with a three per cent. solution of boric acid, or a 1 to 4,000 corrosive sublimate solution, before the injection is made. The puncture should be sealed with iodoform collodion. In favorable cases, although the collection re-accumulates, it is smaller in quantity, and by repeating the treatment every three to six weeks a cure may be looked for in a fair proportion of cases.

BONE AND JOINT TUBERCULOSIS.—The remarks that

have just been made apply with equal force to bone tuberculosis. The iodoform not only has a beneficial effect upon the accompanying abscess-wall, but it is said also to have a curative influence upon the bone lesion.

Tuberculosis of joints has furnished a large field for the use of the iodoform treatment. The mode of application of the remedy should depend upon the condition of the joint. In the condition known as "fungous joint" the injection is to be made into the joint and around the area of disease. If there is fluid this should be aspirated, the joint irrigated with the boric-acid, or mild bichloride of mercury solution, say 1 to 10,000, and the iodoform mixture introduced. The opening is to be sealed with iodoform collodion. If the joint cannot be satisfactorily drained by aspiration, incision should be resorted to, followed by irrigation, the introduction of iodoform, and primary sutures. Moderate rest of the joint after injection is advisable, but it is not necessary to resort to absolute fixation. Massage is not to be recommended, as dissemination of the disease might be thus caused.

De Vos reports sixty-eight cases subjected to this treatment: sixty were joint tuberculosis, six tuberculous fistulæ, and two tuberculous abscesses in connection with diseased bone. Cure is reported in seventy-two per cent. of the cases. The duration of the treatment in the different cases was from nine to three hundred and twenty-five days; the number of injections in a single case from one to twenty; the amount of iodoform used during the treatment of a patient varied between 2 and 67.5 grammes, and the amount of oil from 10 to 385 grammes.

The beneficial effects of the injections consist in a decrease in the pain and swelling, and in connective-tissue formation, at the points of injection. The latter is reported to have been observed in a case which later demanded resection.

De Vos, after conducting a series of experiments on cadavers, recommends the following points for puncturing the various joints: For the *shoulder*-joint, the arm should be adducted and the forearm bent at a right angle across the abdomen. The needle is entered 1 ctm. behind and below the point of the acromion. For the *elbow* a point is selected external to the olecranon, the needle being introduced between the head and the tuberosity of the radius. For the *wrist*, on the radial side, the most dorsal corner of the depression between the extensor tendons at the root of the thumb (*tabatière* or anatomist's snuff-box). On the ulnar side, a point on the upper anterior part of the pisiform bone. For the *hip-joint* de Vos has given the method devised by himself. He first determines a point as broad as the thumb of the patient, external to the middle of the line connecting the anterior superior spine of the ilium and the tuberosity of the pubis. From this point, which lies inside and above the head of the femur, a line is drawn toward the external point of the trochanter major. This latter line is divided into four equal parts. The first dividing point from the trochanter toward the middle is the point which should be selected for puncture. The needle is introduced until bony resistance is felt; the limb should be straight, and the inner border of the foot vertical. This rule holds for the position of the trochanter in the Roser-Nélaton line; but if the trochanter is dislocated, then the starting-point must be transferred in the direction in which the head of the femur is displaced.

Von Büngner recommends Küster's plan, which is as follows: The point at which the femoral artery crosses the horizontal ramus of the pubis is determined by palpation. The puncture is made at the inner border of the sartorius muscle, in the line drawn from the previously determined point to the trochanter major. The needle is passed in a straight direction into the joint. In this position the capsule is punctured at its thinnest point, and in thin persons the head of the femur can be felt. As the capsule extends from the border of the fibro-cartilage of the joint to the oblique line of the femur, a little deviation of the needle will not result in a failure to enter the joint cavity; there are no important structures here to wound, and it is the shortest and most direct route to the joint. For these cases the needle should be from seven to nine centimetres long. Ten grammes of the fluid may be injected at each séance.

For the *knee*, a point between the corner of the upper tibial border, and the ligamentum patellæ; for the *ankle*, a point on the outside of the foot immediately anterior to the point of the external malleolus, the needle being directed toward the calcaneum in order to pass between this bone and the malleolus.

Zinc Chloride.—Lannelongue has proposed the parenchymatous injection of zinc chloride in local tuberculous troubles, and reports good results following its use. His theory is that, as a result of these injections, a mass of new connective tissue is formed about the area, and the organization and contraction encapsulate the focus of disease. He has accordingly applied to this treatment the name "sclerogenous." The remedy is applied by making injections, at several points around the periphery of the diseased area, of a few drops of a 5 to 10 per cent. solution of zinc chloride. These may be repeated at intervals of from one to two weeks, according to the amount of disturbance which follows.

Desguin, Dubois, Coudray, Mauclaire, and other French observers have reported very favorably upon this treatment, but it has not been employed in this country and needs further trials.

Tuberculin.—When tuberculin was first brought to the notice of the profession, it seemed to promise great assistance in the diagnosis and treatment of surgical as well as medical tuberculous diseases. In practice, however, it has been found to be of less service to the surgeon than it was to the physician. Lupus excepted, the treatment of surgical tuberculous affections is much more satisfactorily carried out by other means. At best, under the influence of tuberculin, improvement is very slow, and if the case is amenable to operative treatment this should be resorted to in preference. It is not considered justifiable at present to resort to tuberculin for diagnostic purposes, except in rare cases, although it is probable, as Mr. Watson Cheyney remarks, that the dangers attending the use of tuberculin in surgical troubles have been magnified. A fuller discussion of this subject will be found under "Tuberculin" in this work.

A number of well-authenticated instances are on record in which lupus appears to have been permanently cured by tuberculin, either alone or in conjunction with operative procedures. There is no treatment which has been thus far recommended that would seem to offer as good prospect for cure as the injections of tuberculin, combined with proper surgical measures.

Passive Hyperæmia.—Professor von Esmarch has recently advocated the production of passive hyperæmia as a means of treating local tuberculosis. The theory is based upon the experience of pathologists and clinicians, that the immunity of the lungs from tuberculosis increases with the increase of blood in the lungs, and to the contrary, anæmic lungs are in the highest degree predisposed to tuberculosis.

Bier reports, from Esmarch's clinic in Kiel, 43 cases treated by this method. In 27 of these passive hyperæmia comprised the sole treatment. In the cases of bone and joint tuberculosis the results are spoken of as excellent: inflammation of the sheaths of tendons was improved, a mass of cheesy glands at the elbow became a hard scar, tuberculosis of the skin is reported as cured in two instances. One case of tuberculosis of the cellular tissue was also cured. Lupus was not benefited.

The beneficial results may be explained by the increased nutrition of the part, but a more powerful effect, Bier thinks, is exerted by the passive congestion, which he supposes leads to the formation of connective tissue.

Heller, of Kiel, believes that by the obstruction of the circulation the tubercle bacilli die from their own products. The effect is reported to be better in fresh lesions than those obtained by the use of iodoform.

To induce a condition of hyperæmia, the affected part was subjected to a temperature of from 70° to 100° F. for eight to ten hours, in the first cases. The result was an arterial hyperæmia, with redness, swelling, and

œdema. The results were negative. The plan of treatment adopted at present is the following: Suppose the elbow-joint is the part affected, the fingers, hand, and arm are bandaged up to the articulation, then directly above the joint an elastic band is made to encircle the arm tight enough to impede but not to arrest the circulation. It is necessary to interpose a piece of lint to protect the skin from the direct pressure of the band, and the latter must be changed to a new point from day to day.

TUMENOL. This compound, which is very similar to thiol, has also been proposed as a substitute for icthyol. The mineral oils obtained by the fractional distillation of coal-tar are supposed to contain a class of unsaturated hydrocarbons, which are readily acted upon by sulphuric acid. These hydrocarbons, treated with concentrated sulphuric acid, constitute the active ingredients of tumenol. It differs from thiol by the hydrocarbons not being sulphuretted before the addition of the acid. The process consists in the separation and purification of the hydrocarbons, and then treating them with the acid. The hydro-carbons undergo sulphonation and are separated as a dark, thick liquid, containing sulphone and sulphonic acid, known as *commercial tumenol.* It is a dark-brown, almost black fluid of a syrupy consistency, acid in reaction. *Tumenol-sulphone* and *tumenol-sulphonic acid* may be separated from the commercial tumenol by the addition of soda lye, which combines with the acid to form a soda salt. The mixture is then shaken with ether, which dissolves the sulphone and leaves the salt in solution. The tumenol-sulphone is a dark-yellow, thick liquid; soluble in ether, but insoluble in water. In an aqueous solution of tumenol-sulphonic acid it readily dissolves. Tumenol-sulphonic acid is a dark powder, having a peculiar faintly bitter taste. It is easily soluble in water, and the solution can be evaporated without separation taking place. It is, however, precipitated from solution by the addition of alkalies, with which it combines to form salts.

The therapeutic properties depend upon the antiseptic action and also upon a powerful reducing action which has recently been pointed out. It is recommended in eczema, erosions, ulcerations, and pruritus. In the latter condition it has been found to be particularly serviceable. The value of the compound, as a remedial agent, is not as yet very satisfactorily made out.

The acid and its salts are expensive and have not been employed. The commercial tumenol is that which is generally used. From this two forms of solution are prepared for use, one containing ten per cent. of tumenol in equal parts of ether and rectified spirit and water, and the other containing glycerine in the place of the water. It may also be used as an ointment. The tumenol-sulphonic acid is employed as a powder, or in solutions, of the strength of one or two per cent.

Beaumont Small.

TUNNEL POISONING. Asphyxia, or partial asphyxia, with a general poisoning and consequent disturbance of the system, is frequently met with in the construction of tunnels in the present day, and is due to the use of what are termed "high explosives;" for in the removal of rock in the construction of such work dynamite or nitro-glycerine is used in considerable quantities.

When these are used in open-cut work, as on railroads, after the explosion the gases immediately distribute themselves in the atmospheric air, and no effect has been noticed on the workmen employed. But where it is used in tunnels, as in mining or other partially closed cavities, and the gases or residue are slow to escape from the mouths of the tunnel or up an air-shaft, serious deleterious effects are produced.

Dynamite is composed of nitro-glycerine with some absorbent. There are, for purposes of study, practically two classes of dynamite, which might be termed inorganic and organic, according to the absorbent used. As a type of one class is that made with infusorial earth—Kieselguhr—which is composed of siliceous diatoms, and of the other, that made with ground wood-pulp or sawdust. Others still are made from a combination of both kinds. The results of the explosion, however, are practically the same in either case, except with the organic absorbent we get with the products an additional amount of carbon.

There are two classes of cases of poisoning produced by breathing the products of the explosion of such materials: First, acute cases, where a considerable quantity of the residue is inhaled at one time; and secondly, chronic cases, or where a small amount is constantly breathed for a long time. The acute cases vary according to the amount inhaled.

Where the amount of dynamite used is not large, or where after the explosion a considerable quantity of fresh air has been mixed with the products of the combustion, or where the workman has, after a few breaths, become giddy and is pulled away by others and sent to the surface, the effects produced are a trembling sensation, flushing of the face, succeeded sometimes by pallor, frequently nausea, sometimes vomiting, with throbbing through the temples, and fulness in the head, as if it would burst, followed by an intense headache characteristic of poisoning by nitrites—similar to that of nitrite of amyl, only not so violent, but more persistent, frequently lasting forty-eight hours. The heart's action is increased, and the pulse is full and bounding, though somewhat compressible, and varying in rate from 100 to 140. The condition is described by the workman as a "dizziness." He feels as if drunk, or as if his head is swelled.

In the second class of these acute cases, where a man goes into the tunnel immediately after the explosion, and is brought in contact with a large percentage of the poisonous materials, the effects are giddiness, immediately followed by unconsciousness, and the patient presents the usual appearance of asphyxia.

Sometimes in these cases the pulse is full and bounding, though very compressible, but in most of the cases it is alarmingly weak. Generally there is a great pallor, though this may be partially due to working underground. The comatose condition soon passes away, and is succeeded by drowsiness, languor, cold perspiration, intermittent pulse, and generally nausea and vomiting. Sometimes the breathing is spasmodic, and frequently there is hiccough, and after a time a severe headache.

Nearly all of these cases, however, no matter how serious they seem at the time, recover. Though in cases where death does occur, it is usually several hours after the patient has been removed from the tunnel, and is due to paralysis of respiration.

In the chronic cases, where but little of the products are breathed daily, there are four prominent symptoms: These are headache, cough, indigestion, and disturbances of the nervous system. The headache is usually a continuing one, and varies in degree from a mere fulness to a throbbing pain. The cough is similar in character to the cough of pertussis, or of malaria, and as cases of ma-

laria are frequent upon such works, one may easily mistake the cause.

Next in prominence to these symptoms come disturbances of the nervous system, as trembling, irritability, neuralgia, etc. In fact, nearly, if not all, of the symptoms are attributable to this cause. Even the cough is, in all probability, due to the effect produced on the pneumogastric nerve.

With this nervousness is also associated indigestion, probably due to the same cause. Of course, with this latter symptom, the character of the food and the manner in which it was eaten must be taken into consideration; but as soon as a man with these chronic symptoms is taken from the tunnel and placed at work on top he steadily improves, and finally entirely recovers.

It is also noticeable that those who have previously suffered from dyspepsia, or from tic douloureux, or sciatica, or other form of neuralgia, are made worse by the dynamite smoke.

What are these symptoms due to?

The formula for nitro-glycerine is $C_3H_5(NO_3)3$. And the products from the combustion of this are written: $4(C_3H_5N_3O_9) = 10(H_2O) + 12(CO) + 6(N_2O_2) + O_2$.

In other words, the products are water, carbonic oxide, and nitrogen dioxide, none of which would produce the symptoms above described except asphyxia.

A comparison of the above symptoms in the acute cases, with the phenomena produced by various-sized doses of nitro-glycerine, shows them to be identical. This similarity between the symptoms from inhalation of the products of the explosion of dynamite, and those produced by the nitro-glycerine itself, is so well marked that even miners themselves have noticed it. Frequently, when dynamite is frozen, a miner will place a cartridge in his boot to thaw it out, and the absorption of nitro-glycerine through the skin will produce precisely the same symptoms as in the mild acute cases of the inhalation of the products before described.

Again, as another instance, a miner used his knife to cut a cartridge and afterward ate an apple cut with the same knife. In this case, according to his statement, the symptoms were similar to being "knocked out by powder smoke," only more severe; the headache persisting three weeks.

And on another occasion this same miner cut up some tobacco to smoke with a knife that he had used for dynamite, and was again similarly affected. Here the heat from the tobacco smoke volatilized the fine particles of nitro-glycerine on the tobacco below, and poisoning was produced by absorption through the lung tissue. No other conclusion can well be reached than the fact that there is mixed with the gases produced unexploded particles of nitro-glycerine in a volatile state; and these particles inhaled by the miners produce the effect described.

This fact can be conclusively proved by waving in the fumes, immediately after an explosion, a cold sheet of glass, and thus collecting upon it by condensation a small percentage of the nitro-glycerine itself.

There is no doubt but that the explosion of a large quantity of dynamite would produce sufficient gases of CO and N_2O_2 to produce asphyxia. Here we get the cyanosis and other symptoms of simple asphyxia, and we may get nausea and vomiting; but not the same disturbance of the sympathetic system, nor the continued chronic spasms of the vagus, nor the persistent headache pathognomonic of nitro-glycerine poisoning.

As regards treatment, as a preventive, the use of such apparatus or machinery, whether by blowing or by sucking, that will rapidly clear the tunnel or cavity from noxious gases or fumes, is to be recommended. Where steam drills that are worked with an air-compressor are used, they contribute largely to this end.

Also, it has been found by makers of dynamite that the use of a large cap will explode a greater percentage of nitro-glycerine than a small one, and this, to a certain extent, obviates the trouble. In certain cases, however, for some reason a cartridge does not explode, but burns like a candle, with considerable spluttering. In such an instance the amount of nitro-glycerine volatilized is much greater than if exploded, and consequently the effects are more deleterious. For immediate treatment, such measures as are generally used in cases of asphyxia are of service.

In addition, the use of cold to the head or the subcutaneous administration of atropine, ergotine, or other vaso-motor stimulant, is of necessity indicated and exceedingly efficacious. There is little doubt that the effects of nitro-glycerine are produced from its decomposition and the formation of a nitrite in the body. "Treatment with ammonia restores normal color and normal functional power to nitrite-poisoned blood." So the carbonate and aromatic spirits of ammonia should be used internally, and it is also well for those in charge of such works to recommend to the workmen employed to carry with them small vials of this remedy for use in such cases. *Thomas Darlington, Jr.*

TWIN PREGNANCY, COMBINED INTRA- AND EXTRA-UTERINE. This title is lengthy, but it names its subject completely, *i.e.*, this caption indicates twin gestation, wherein one fœtus is situated normally in the uterus and the other fœtus lies external to the uterine wall, but is abdominally enclosed; or, in other words, there is normal uterine gestation co-existing with ordinary ectopic pregnancy.

This is a rare combination of affairs, and apparently but few are aware that it ever existed, as nearly every observer has stated, voluntarily, that they did not know of such a thing until they met it accidentally in practice. Surely this was the writer's experience in his own and only case, which occurred in November, 1889, and so far as he knows is the last case put on record. The first case for which there is proper authority was reported by Duverney, and occurred in 1708. Twenty-five cases have been reported, and possibly more. The literature is scarce, indeed, upon this subject, only a few of the recent authors treating upon this condition at all, and they rarely do more than merely suggest that such an occurrence has been known.

Cause.—But little can safely be said upon the etiology. It appears that twin pregnancy is much more frequent in extra-uterine pregnancy than in uterine pregnancy, and it has been suggested that one *ovum* obstructs the other in the passage along the Fallopian tube, thus forcing one back into the abdomen or arresting its transit, while the other passes on into the uterus. This could scarcely be so, unless the two embryos develop from different ova, and only one ovary contributes.

Diagnosis.—The symptoms and history by which combined intra- and extra-uterine twin pregnancy is to be recognized, are those of ordinary ectopic pregnancy coupled with normal, or uterine, gestation, which latter, to avoid error in diagnosis, may be entirely ignored. It should be remembered that pain in the lower abdomen and symptoms of internal hæmorrhage, accompanied by evidence of normal pregnancy or a recent abortion, does not preclude the possibility or probability, if the symptoms are marked, of extra-uterine pregnancy coexisting with the uterine pregnancy. In other words, and for the sake of emphasis, it may be repeated, the very fact of uterine conception, or its history existing, may for all practical purposes be disregarded, and the diagnosis of abdominal pregnancy alone be considered in arriving at a correct knowledge of the case.

Should the case continue to the ninth month, which is quite probable unless terminated at about the third month, and after the birth of the uterine child, there will be very little difficulty in concluding the diagnosis, for the second child does not descend, although there may be terrific labor pains in the attempt of nature to throw off the supernumerary fœtus. Then the hand passed into the uterus for exploratory purposes (though probably it will be done for version) will find the uterus empty, and through the thin uterine walls it will be able to make out another child outside of the apartment in which the hand is. The next question to decide is whether the attendant has a *uterus bicornus* to deal with; this he does

by seeking for another *os*. Failing to find this, he need have no doubt as to the nature of the condition.

Treatment.—The fact of normal gestation existing will not excuse one in neglecting the symptoms of extra-uterine pregnancy; and should there arise at the third month, or thereafter, the alarming indications of rupture of the sac and abdominal hæmorrhage, the case should be dealt with in the usual way of treatment for extra-uterine pregnancy; or should the true condition be recognized before rupture occurs the case may be cared for by electrolysis, or otherwise, as the attendant desires.

When death of the fœtus occurs at an advanced state, say from the fourth to the sixth, or seventh, month, it will be found that nature has made an effort to get rid of the dead fœtus, in most of the cases collected, by means of breaking down of tissue, or by finding an exit through the bowels or through the abdominal parietes. The treatment of such a case will be suggested as time advances and the condition of the mother indicates.

Strange to say, very nearly half the cases thus far noted have continued to the ninth month, and over fifty per cent. of this number have made a complete recovery with little other assistance than that of unaided nature.

The great difficulty of doing a primary operation lies in dealing with the placenta. If it is removed the woman dies of hæmorrhage, and if left to come away by drainage and sloughing she dies of septicæmia, an equally insurmountable obstacle. In the writer's case a healthy female infant was born at term, and at the same time a full-grown child was left in its abdominal *sac*. Hard labor pains followed for ten whole nights in succession, with entire intermission in the day-time, and these pains were only controlled by large doses of opium. The woman made a good recovery. Shrinking began at once and continued so that at the end of three months all that was left of the fœtus and its secondines was a mass not larger than the medium-sized fist of a man. This tumor has never given the woman any inconvenience since the first month, though she has not since become pregnant. Out of the eleven cases that have gone to term seven have recovered entirely when treated expectantly, while in every case in which primary laparotomy was performed the mother has died, though both children have been saved.

It is hoped that through the agency of modern surgery and modern cleanliness, some means will be devised for successfully coping with a contained placenta.

A. H. Harriman.

TYPHOID FEVER. During the seven years which have elapsed since the publication of the original article in Volume III. of this HANDBOOK, comparatively few additions have been made to our stock of knowledge with regard to typhoid fever, and these few belong almost wholly in the department of therapeutics. In discussing these new facts we shall follow, as nearly as possible, the subdivisions adopted in the section on treatment, in the original article.

DIET.—In speaking of the employment of milk as an article of diet in typhoid fever, we said that when it was found that even small quantities disagreed with the patient, lime-water or one of the aërated waters might advantageously be added to it, or it might be boiled. We would add that if the milk is very rich it should be skimmed, and the addition of lime-water in the proportion of from one-sixth to a quarter of the volume of milk is generally indicated. Furthermore, it should not be forgotten that a given solid may be more digestible and less irritating in the stomach and intestine than a given liquid, which subsequently becomes a solid.

Diet in Convalescence.—The value of the old rule—to wait a week after the evening temperature has fallen to normal before increasing the diet, either in amount or in-consistency—is still recognized. After this period, however, considerable variety may be introduced into the dietary list. To the items enumerated in the original article, two others may well be added, viz., a tender, juicy chop, or a bird well cut up. In deciding of what the diet shall consist, on any particular day, we must, of course, keep in mind both the vigor of the patient's appetite and the height of the body temperature. Convalescence is sometimes unnecessarily prolonged by the lack of suitable or sufficient nourishment. On the other hand, some practitioners would be even more liberal in their dietary. So good an authority as Peabody, of New York, thinks, "we are accustomed to have too great a dread of doing harm at the site of lesion in the ileum in typhoid fever by giving solid food. If I am correct in my opinion as to the inference to be drawn from hunger in a fever patient, there is even less likelihood of causing damage to an ulcerated ileum by giving finely divided egg or beef or chop to such a patient than by giving him milk; and my experience seems to justify the inference. It has been my practice for years to allow albuminous foods of these descriptions to such patients, even before the fever leaves them, under these conditions. I have at present under treatment several patients with typhoid fever whose temperatures reach 101°, 102°, and 103° F., daily, who are hungry, and who are receiving such solid food once a day. So far as I am aware, I do not have a larger percentage of relapses or hæmorrhages or other serious complications or accidents in my practice than I did before I adopted this plan, or than my colleagues do who have not yet adopted it."[1]

Bowels.—Within the last few years a variety of drugs have been tried with a view to intestinal antisepsis, to the prevention of intestinal fermentation and formation of those poisonous and depressing alkaloids which are supposed to be elaborated freely in the fæces of the typhoidal bowel. In regard to some of these drugs, F. P. Henry[2] says that it is a well-known chemical fact that they destroy the toxic intestinal alkaloids, and that it is admitted by all who have given them a thorough clinical test that they exert a most favorable influence upon the course of typhoid fever. Osler,[3] on the other hand, testifies to the inefficiency of the carbolic acid and iodine and of the beta-naphthol treatment, and congratulates the patient that the majority of these medicines meet one of the two objects which Hippocrates says the physician should always have in view—they do no harm.[3]

Among the various other agents employed may be mentioned thymol, corrosive sublimate, naphthalin, hydronaphthol, the salicins, salol, iodoform, charcoal, sulpho-carbolated water. Henry, in commending Bouchard's dictum, that an intestinal antiseptic should be more or less insoluble and exert no toxic effect on the organism, ranks thymol as the best of these agents. He favors its use as unreservedly as does Brand that of cold water tubbing. In every case in which he has employed thymol in an early stage of the disease, the tongue has become rapidly clean and moist, and has so continued; tympany has speedily subsided, or has never made its appearance; diarrhœa has diminished, without being followed by constipation; there has been no delirium; and finally the temperature has gradually subsided and remained within natural bounds. In a word, the typical symptoms of typhoid fever will, according to his experience, rarely develop if thymol is administered during the first week of the disease. He states that its antiseptic power is four times greater and its poisonous effects ten times less than carbolic acid. It is, secondly, so insoluble as to reach the small intestine, and there exert its antiseptic effect. It should be given in pill form. The usual dose would be one two-and-a-half grain pill every three hours, a maximum dose two such pills every three hours. Each pill should be followed by enough water to insure its rapid passage into the stomach, and thus avoid the disagreeable burning sensation to which it might otherwise give rise.

Pepper, of Philadelphia, is equally convinced of the merits of nitrate of silver, which does not meet Bouchard's requirements of an intestinal antiseptic. He gives

it in pill form in doses of one-fourth to one-fifth of a grain from the earliest moment at which the disease is suspected until the entire close of the process.

Perforation, according to Murchison, occurred in 11.38 per cent. of 1,721 fatal cases collected from various sources; Hölscher[4] found 5.7 per cent. among 2,000 typhoid autopsies at the Munich Pathological Institute; Fitz, of Boston, among 4,680 cases of typhoid fever, tabulated by various authors, finds a mortality of 6.58 per cent. from perforation;[5] and Mason, among 676 cases tabulated at the Boston City Hospital, finds 2.7 per cent.[6] Although this accident occurs most often toward the end of the second, and during the third and fourth weeks, it may take place at any time from the first to the sixteenth week. Immediate laparotomy for the relief of suspected intestinal perforation in typhoid fever is only to be advised in the milder cases of the disease (Fitz[7]). In all others, evidence of a circumscribed peritonitis should be awaited, and may be expected in the course of a few days. Surgical relief to this condition should be urged as soon as the strength of the patient will warrant. Immediate operation may also be indicated when the perforation occurs during early convalescence.

Of 27 cases of peritonitis in typhoid fever, whatever the cause of the former, though often attributed to intestinal perforation, 3 recovered after operation, 17 after resolution, and 9 after the spontaneous discharge of pus.

Van Hook, of Chicago, has reported three laparotomies for perforation, not included in the above, of which two were followed by death and one by recovery.[8] All three operations were performed soon after the symptoms manifested themselves, but in the successful case the perforation occurred on the eighth day of a relapse following three weeks of a first attack.

The positive diagnosis of perforation may be comparatively easy or it may be very difficult, and the diagnosis must justify the operation.

Pyrexia and Hyperpyrexia.—The present tendency of medical opinion is toward the view that pyrexia, apart from infection, is comparatively innocuous; that temperature is an indication, and not a condition; that the reading of the thermometer should be controlled by the character of the pulse and the general systemic condition. It is to be remembered that one patient with a high temperature may be really less sick and in a less dangerous condition than another with a lower temperature. Granted this, however, the temperature is, in a general way, still the index and the measure of the progress of the disease, and of the indications for interference with its natural course where such interference is resorted to, and that whether the therapeutic measure adopted results in heat-repression or heat-abstraction. Moreover, a continuous high temperature is, as a rule, accompanied by a less favorable systemic condition than an intermittent or remittent temperature which reaches temporarily a higher maximum. An evening temperature of 102°, or even 103° F., with a morning remission, may be regarded as the normal and moderate result of the typhoid process. An evening temperature rising above 103° F., especially if the morning remission be slight, suggests the propriety of interference and the abandonment of mere expectancy. The various forms of active interference with the course of the typhoid process, as represented by temperature, may be classed under the two heads of (1) the external application of cold, and (2) the internal exhibition of drugs.

1. *The External Application of Cold.*—Cold may be applied externally by means of sponge baths, the wet pack, sprinkling the exposed surface of the body, putting the patient in the cold bath, exposure to cold air, or the application of coils of tubing. And here we may be permitted to repeat, with certain modifications and additions, what we said on this part of the subject in our first article.

Sponge Baths with water at a temperature of 70° to 75° F. are grateful, refreshing, tranquillizing, keep up the action of the skin, can be given without fatigue to the patient, and, if frequently repeated, will exert a certain positive effect upon the temperature and nervous system. They are not, however, efficient in controlling a marked hyperpyrexia. The wet pack, or sprinkling the body, covered only with a sheet, has a more pronounced action. The cold bath is still more effective.

Cold Baths.—In regard to cold baths, it may be said, in general that mild cases do not require them, and in advanced cases—after the second week—they are less safe. Great care must be exercised in giving them to young children and old persons. The patient should always be carefully watched, and the administration of some form of stimulant, either during or after the bath, is often indicated. The bath should be rolled to the bedside, and at least two attendants are required, that as little fatigue as possible may ensue to the patient when being lifted in and out. The bath may be given as a cold bath, at a fixed temperature of from 65° to 70° at the outset, or as a graduated bath, the water being gradually cooled from 85° to 65° F. The graduated bath consumes more time, and for many patients is quite as much of a shock as the cold bath. With either method the pulse must be carefully watched. In the cold bath, fifteen to twenty minutes will generally suffice to produce shivering, when the patient should be removed. During the bath cold water should be poured upon the head and friction of the surface of the body should be kept up. It is to be borne in mind that the temperature almost always continues to fall considerably after removal from the bath. When the temperature returns to the initial point the bath is to be renewed. In this way five or six baths may be required in a single day. It is claimed by the advocates of this treatment that it should be commenced early in the disease, before the fifth day, and steadfastly persevered in to secure its full advantages. It has been accused of increasing the tendency to relapse and to intestinal hæmorrhage, but statistics do not seem to bear out this view. It certainly involves some disturbance to the patient, and an increase of labor on the part of attendants. Dr. Brand, of Stettin, formulates his method thus: Baths of 64° to 68° F., of fifteen minutes' duration, must be administered from the fifth day of the fever, and be repeated day and night, every three hours, as long as the temperature of the rectum exceeds 102° F.; he also affirms that every case of typhoid treated thus, regularly from the beginning, will be free from complications and will get well.

Since the introduction of the systematic use of cold baths (cold water had often been used in earlier times) in 1861, the typhoid-fever death-rate in the German hospitals, the Prussian and Bavarian armies, has shown, according to most of the available statistics, a very marked decrease. Brand offered (1887), from 23 German and French sources, the reports of 5,573 cases treated by his system of cold baths with a mortality of 3.9 per cent. Eliminating from these the cases imperfectly managed, he reports 1,223 cases treated strictly in all details, according to his rules, by Jürgensen, Vogl, and himself, with a mortality of 1 per cent. In his private practice he reports a considerable series of cases without any death.

In this country, J. C. Wilson reports 226 cases treated by the Brand method at the Germau Hospital, Philadelphia, between February, 1890, and June, 1892, with a mortality of 5.3 per cent. The number of baths in individual cases varied from 1 to 148, the average being about 43. The average number of days in the hospital of the non-fatal cases was about 35. Relapse occurred in 12 per cent. of the cases.[9]

Drs. Peabody and Baruch, of New York, have used the Brand method in hospital and private practice, and are strong advocates of its more general adoption.

Dr. F. E. Hare, of the Brisbane Hospital, Queensland, reports 1,828 cases treated by the expectant or general method, with a mortality of 14.82, and 1,173 cases treated by cold baths with a mortality of 7.84 per cent.[10]

Dr. F. C. Shattuck reports 129 cases treated at the Massachusetts General Hospital in three successive years, without cold baths but with sponging, with a mortality of 8.37 per cent.[11]

Dr. A. L. Mason has tabulated 676 cases admitted to

the Boston City Hospital in 1890 and 1891, and treated without cold baths—sponge baths being used when indicated. The mortality was 10.4 per cent. There were, however, 54 consecutive cases without a death; and the mortality-rate should be considered in the light of the following controlling conclusions:[12]

1. That in the Boston City Hospital the mortality in typhoid fever from patients admitted moribund and with grave complications is 4 per cent.

2. That at least 3 per cent. more die from intestinal perforation and hæmorrhage.

3. That little diminution in the mortality from these causes can be expected under any mode of treatment.

4. That the mortality from renal, pulmonary, and circulatory disturbances, from diarrhœa and pyrexial exhaustion, is about 3.5 per cent.

5. That, excluding deaths from intestinal perforation and hæmorrhage, the mortality among females is 3.4 per cent. greater than among males.

6. That a diminution of 3 per cent. in the general mortality might be expected from the systematic use of cold baths, the reduction being largely in females.

7. That favorable results followed the trial of intestinal antiseptics, but that relapses were not prevented thereby, and that a much wider experience is necessary to determine their value.

L. Riess, of Berlin, has treated typhoid fever with a prolonged bath at a temperature of 88° F. The patient is supported by a hammock and is placed in the bath whenever the rectal temperature reaches 102° F., where he remains during the day and night, if necessary, until the rectal temperature falls to 100° F. The same process is repeated whenever the temperature rises to the initial point. Riess claims a reduction in the rate of mortality and a diminution in the average duration of the disease among 809 cases treated.[13]

Dr. James Barr, of Liverpool, has made use of a permanent bath, and reports 2 deaths out of 71 cases, the most serious of which were treated in this way.[14] The patient, wrapped in a blanket, lies, on bed-ticking stretched across a tank, under water. The head is sufficiently raised. As long as the patient's temperature in the mouth is over 100° F., the temperature of the water in the tank need not rise above 90° to 93° F., but as the body temperature approaches the normal so should the temperature of the water. Barr did not find it necessary to lower the temperature of the water below 90° F., nor to raise it above 98° F. Patients were kept in the tank for varying periods, from a few days up to thirty-one days.

Barr is evidently satisfied with his results, and his "statistics," though based on a small number of cases, are very favorable. He proposes to perfect the details of his method.[14]

It is evident that we have not yet had the last word in regard to the cold-water treatment.

2. *The Internal Exhibition of Antipyretics.*—The internal use of antipyretics, and especially of the synthetic laboratory compounds, has not answered all the expectations which were entertained in regard to them at the time of their first introduction, though I am inclined to think that the reaction against the intelligent use of the best of them has gone somewhat too far. They cannot be used repeatedly and systematically, as can the cold baths, neither do they, in moderate quantities, modify appreciably the course of the disease, as is claimed for the baths. But their occasional administration, under suitable conditions, does substitute calm for excitement and sleep for restlessness, leaving the patient refreshed rather than depressed. The best of them are antifebrin (acetanilide) and phenacetine. The antipyretic action of the former is the more marked, and the analgesic action of the latter. Antifebrin may be given in doses of from two to five grains, and phenacetine in doses of from five to ten grains.

The Poison of Typhoid Fever.—That typhoid fever is a specific disease, propagated by a specific poison, is scarcely questioned to-day. That Eberth's bacillus is constantly present in some of the tissues and organs, and that its presence is in some way responsible for the disease is also pretty generally admitted by the most competent investigators. There are some, however, who, though recognizing its accompaniment of the disease, are unable, from the anatomical point of view, to accept it as a cause of the conditions found. Its pathogenic power may depend upon the formation and absorption of toxic substances resulting from its life processes (ptomaïnes ?) rather than upon the multiplication of the bacillus in the tissues of its victim. Eberth first described this bacillus in 1880, and demonstrated its presence in the spleen and diseased intestinal glands of typhoid cadavers. Gaffky (1884) first obtained pure cultures and determined its principal biological characters.

It is a short, thick rod, three times as long as broad; 3 μ in length, 0.5 to 1 μ broad; about one-third as long as the diameter of a red blood-cell; it has round extremities where spherical or oval refractive granules are often seen, which have been regarded by some as spores and by others as vacuoles. It stains with the aniline colors, but more slowly than many other bacteria, and easily parts with its color when treated with decolorizing agents. The mode of growth on boiled potatoes, as a nearly invisible pellicle, is its most marked culture characteristic, though Babes, Pfuhl, and other bacteriologists, affirm that many bacilli resemble the typhoid bacillus in their growth upon potatoes. It is certainly not easily differentiated from other bacilli (water bacilli) and especially from the bacillus coli communis, and its detection in water is for this, as well as for other reasons, very difficult. Theobald Smith claims (Centralblatt f. Bakteriol., Bd. xii., p. 357) that it may be differentiated from other similar bacilli by the fact that it does not produce gas in culture media containing sugar.

Sternberg found the thermal death-point to be 56° C., and the time of exposure ten minutes.

In his address before the International Medical Congress at Berlin, in August, 1890, Koch made the following statement: A very characteristic example of the difficulty with which the determination of a (bacterial) species is surrounded is exhibited by the bacillus of typhoid fever. If this be found in the glands of the mesentery, in the spleen, or in the liver of a typhoid victim, there can be no question but that we are dealing with the real typhoid bacilli, since no other bacteria have hitherto been found in these regions which could be confounded with these. But when we are dealing with the determination of typhoid bacilli in the contents of the intestine, in soil, in water, or in dust, the circumstances are very different. In such places there are found numerous bacilli similar to those of typhoid which only a very skilful bacteriologist, and even then not with absolute certainty, can distinguish from the typhoid bacillus, since unmistakable and constant characteristics of the latter are, as yet, wanting.

The statements repeatedly made of late that typhoid bacilli have been detected in soil, in water-supplies, or in foods, can, therefore, be accepted only with a reasonable doubt. Babes, while denying that the special single characteristics previously laid down are trustworthy, still thinks that, by taking them altogether, one obtains a very reliable picture of this bacillus.[15]

Sedgwick, from a very careful study of an epidemic in Lowell and Lawrence, Mass., 1890 to 1891, thinks the history indicates that the living and active bacillus can be carried nine miles in river water, and under favorable conditions an even greater distance.[16]

In man it is found most constantly and most numerously in the intestinal contents, in the intestinal and mesenteric lymph glands and nodes, and in the spleen, where it occurs in larger and smaller masses and clusters as scattered colonies. It may be found, though less constantly, in the liver, kidney, and lungs. It occurs in the urine. Statements as to its presence in the blood are contradictory.

Veterinarians do not recognize any disease in animals corresponding to typhoid fever in man. Inoculations of the bacillus into some of the lower animals have caused death with symptoms and lesions which have been re-

garded by some experimenters as resembling those of typhoid fever in man; but there is no consensus of opinion on this point, inoculations with other micro-organisms do produce similar effects, and the evidence is by no means satisfactory.

Nevertheless, the presence of Eberth's bacillus in a *considerable proportion* of cases examined, according to some bacteriologists; its *constant* presence, according to others, in all cases of typhoid fever; the failure to find it hitherto in other diseases; its compliance with many conditions requisite for the "germ" of a disease with the known history, mode of propagation, and life of typhoid; the failure hitherto to establish any probable rival, all tend to support the acceptance of the etiological relation of this bacillus to this disease. Delafield and Prudden consider that the evidence that typhoid fever in man is produced by the "typhoid bacillus," and by this alone, is so strong as practically to amount to a demonstration.

Disinfection and Disinfectants.—The following is substantially the method in use at the Boston City Hospital. The disinfectants used will doubtless vary from time to time, according to the views held as to their action upon the typhoid poison.

1. In all cases of typhoid fever rubber sheets are to be used on mattresses.

2. Bed and body linen are to be changed daily. Bed-spreads, blankets, and rubber sheets are to be removed at once, when soiled by the patient. Avoid shaking any of these articles.

3. All bed-linen, body clothes, and bath towels, soiled by discharges, are to be immediately wrapped in a sheet wet with a solution of corrosive sublimate (1 to 1,000), or carbolic acid (1 to 20), and removed to the rinse-house as soon as possible, where they should be soaked in the disinfectant solution and then boiled before being washed. Rubber sheets are to be thoroughly washed in a solution of corrosive sublimate (1 to 1,000), rinsed with water, dried, and aired for six hours. Bed-spreads and blankets are to be aired as frequently as possible.

4. Feeding utensils are to be thoroughly cleansed with boiling water immediately after using.

5. Dejections are to be received in a bed-pan containing four to eight ounces of disinfectant solution (chloride of lime, 1 to 32) or milk of lime. The nates are to be cleansed with paper, and afterward with a bit of compress cloth wet with the disinfectant solution largely diluted. Milk of lime may be prepared by sprinkling one quart of water gradually upon a quart of quick-lime in broken pieces in a metallic or wooden vessel. When the lime is reduced to powder, three quarts of water should be added, and the whole kept in a covered vessel. Chloride of lime should be fresh.

6. Bed-pans are to be at once removed, being covered with a rubber cover, and taken to the slop-hopper. Add half a pint of disinfectant solution, in divided portions, to the contents of the bed-pan, mix thoroughly by shaking or breaking up solid particles, and throw the liquid into the slop-hopper, which must be previously flushed with running water. The bed-pan, rubber cover, and slop-hopper are to be cleansed with disinfectant solution, and the bed-pan and cover wiped dry. The compress cloth should be burned at once.

7. After the discharge of the patient, mattresses and pillows are to be thoroughly beaten and aired in the open air. The bedstead is to be washed with a solution of carbolic acid (1 to 20).

8. The body of any patient dying of typhoid fever is to be washed in the disinfectant solution, largely diluted, and then wrapped in a shroud-sheet wet with solution of corrosive sublimate (1 to 1,000). *George B. Shattuck.*

TYPHOID FEVER IN CHILDREN. Frequency.—Typhoid fever occurs frequently in children between the ages of five and fifteen. In those between two and five years cases are rare, and in those below two years extremely rare. Murchison[1] gives a list of the few recorded instances in the fœtus and new-born. Northrup[2] has questioned the existence of the fever in children under two years, pointing out that "swollen Peyer's, mesenteric lymph nodes, and spleen in such cases, cannot safely be interpreted like similar lesions in adults." His reasons are that he has found not infrequently, at autopsies of infants under two years, these appearances following many different intestinal diseases, and that in a number of such instances bacteriological investigation has been made, and in no case has the bacillus of Eberth been found. Neuhauss,[3] however, has found this bacillus in the organs of a four months fœtus, and many pædiatrists have seen cases under two years of age with a history of exposure, a characteristic temperature curve, rose spots, and an enlarged spleen.

Pathological Anatomy.—In children the Peyer's patches and solitary follicles become enlarged, and then frequently undergo immediate resolution without ulceration. In many cases, however, there is some superficial necrosis and sloughing, but the resulting ulcers, as a rule, heal promptly. Rarely is an ulcer deep, and very rarely is there perforation. The spleen is usually, but not invariably, enlarged.

Symptomatology.—In children above ten years the disease tends to take on the adult type. Below that age the course is usually shorter and less marked by severe symptoms, and the prognosis is, as a rule, better.

Prodromal Period. — There may or may not be a prodromal period characterized by fatigue in the daytime, restlessness at night, frequent frontal headache, and no appetite. Prodromal symptoms of any sort are usually absent in the very young, but in older children they continue from a few days to two weeks. The exact beginning of the fever is usually doubtful, and the more doubtful the younger the patient. Sometimes the onset is marked by a chill or by chilly sensations, sometimes by an attack of vomiting. Rarely is there an abrupt rise in temperature. Oftenest there is a gradual rise extending over several days.

Temperature.—The rise of the first few days is more rapid than in adult life, for though the ascent is made in the same way with morning remissions and evening exacerbations, the remissions are less and the exacerbations greater, so that not infrequently a temperature of 104° F. is reached by the evening of the fourth day. This fever is subject to daily remissions of one to three degrees, but continues high for sometimes ten days or longer, and then subsides by lysis, which, like the ascent, is usually much more rapid than in adults. The fall usually takes from two to five days, but there may rarely be a crisis. The fever may subside immediately after reaching its height, so that the normal temperature is regained in two weeks or even less. Remissions and exacerbations are most marked in infantile typhoid, and cases are recorded in which the morning temperature throughout the course rose scarcely above normal, while the evening temperature was 102° to 103° F. Cases are seen, too, in which the temperature during the entire course does not rise above 102° F., though the usual maximum temperature is from 103.5° to 104.5° F. A double daily temperature curve, with the exacerbations at about 4 P.M. and 9 P.M., has been frequently noted, and is considered by Jacobi[4] of diagnostic importance.

Circulation.—Some weakening of the first sound of the heart is common in the second week, but cardiac murmurs are rare, though a faint systolic apex murmur

is occasionally developed during the fever only to disappear during convalescence. The pulse in a general way corresponds to the temperature, and averages between 110 and 130, the younger children having, of course, the higher rate. Exceptions are, however, not uncommon. The rate may be moderate, 90 to 100, with a temperature of 103° F., and Henoch[5] has seen it 180 in a case which recovered. A dicrotic pulse is rarely met; an irregular and scarcely perceptible pulse is not uncommon.

Epistaxis occurs, as with adults, frequently enough to be of value in the diagnosis. It appears usually in the latter half of the first week.

Respiratory System.—The respiratory rate is accelerated with the fever, and there is in considerably more than half the cases a cough. Even when the cough is not present, examination of the bases of the lungs behind will after a few days usually show numerous dry and moist râles.

Broncho-pneumonia is common in weak, poorly-nourished children, and may be developed in stout children if the fever is severe. Lobar pneumonia and pleurisy occur, but are rare.

Digestive System.—The tongue is commonly clean and red at the edges and tip, and has a moist, yellowish-white coat over the dorsum; sometimes there are superficial ulcerations on the surface. The tremor of the tongue which is so characteristic in adults is less frequently met in children. Sordes is uncommon, but the lips are frequently cracked and crusted.

Vomiting is a common, early symptom, but is not severe and rarely persists into the second week. There may be diarrhœa or constipation, and either may persist throughout the disease or be present at any period. It is rare, however, for diarrhœa to be entirely absent. It may be noted simply as slight looseness of the bowels, and it may be shown in fifteen or twenty stools in the twenty-four hours. The stools may be foamy, brown, and offensive, or simply yellow and thin, or absolutely normal in appearance. Typical "pea soup" stools are the exception.

The abdomen is usually very slightly prominent and tympanitic. Sensitiveness localized in the ileo-cæcal region is not marked, and its detection in children is usually doubtful. Slight general abdominal sensitiveness is, however, common. Complaint of some abdominal pain is frequently met as an early symptom, and colicky pains, especially before a movement of the bowels, are not uncommon later. Melæna is rare, but Earle[6] has had a fatal case in a child twenty-two months old.

Spleen.—The spleen may be enlarged so that its tip goes to the edge of the ribs, or from half an inch to an inch beyond. It is palpable in a certain small percentage of cases, and may become so by the third or fourth day, though it is not usually so before the eighth day. Henoch[5] did not find the spleen palpable in half the cases in which a careful examination could be made. Determination of increased size by percussion is extremely difficult, and the result usually unreliable. There is often sensitiveness on pressure over the site of the spleen.

Nervous System.—Frontal headache is nearly constant in the prodromal period and during the first week. Delirium begins earlier than in adults, and slight "wandering" may appear even on the second night. Active violent delirium occurs more in older children, but is not rare. In mild cases, however, by day, the child often wants to sit up and to play, even when the temperature is considerably elevated. In severer cases the child becomes speedily apathetic and somnolent. Crying at night, grinding the teeth, twitching of the muscles of the face and of the wrists, stiffness of the posterior cervical muscles, may all be met in severe cases. Convulsions and coma occur, but are rare. Partial or complete deafness is frequently met during the fever, and may persist for weeks. Aphasia occurs more frequently than with adults, and appears commonly at the end of the fever or during convalescence. It may persist for a few days or a few weeks. Hyperæsthesia is common and unimportant. Involuntary evacuation of the bowels is rare, as is bladder retention, but both occur. Forgetfulness and silliness are apt to be noted for a considerable time during convalescence.

The Skin.—The roseola may or may not be present. If present its first appearance is earlier than in the adult, and may be noted between the fourth and tenth days. The eruption lasts about a week. The spots are not peculiar in children, but their number is usually less, two to ten often; still the crop has been so abundant as to be taken for measles.

Duration.—The duration varies greatly in different cases. Henoch in eighty children found periods varying from one week to seven. Three weeks is an average length for the fever, but if the case has been at all severe prostration is marked and convalescence is slow, frequently lasting four or five more weeks.

Relapses.—Relapses occur as with adults, and usually run a brief and mild course. The interval between the fever and the relapse varies from two or three days to a couple of weeks, and the relapse may last from one to three weeks.

Prognosis.—A larger percentage of children recover than of adults, but under two years the prognosis is grave. Convalescence is long and its period is marked by an increased liability to take other infectious diseases, and by persistent feebleness of the mental faculties. (West.[7])

Diagnosis.—The diagnosis is reached always by exclusion, but the symptoms which are most important for a conclusion are: 1, characteristic fever; 2, gastro-intestinal disturbance; 3, bronchitis; 4, roseola; 5, headache; 6, characteristic tongue.

To be excluded are: pneumonia, gastro-enteritis, influenza, pyæmia, chronic tuberculosis, acute tuberculosis, tubercular meningitis, and malaria. Careful repeated examinations of the chest will decide the question of pneumonia, and examination of the blood will do the same for malaria. Pyæmia is usually secondary to bone disease, and the variations in temperature are more irregular and extreme than with typhoid. Chronic tuberculosis shows marked changes in the lungs, and the temperature is pyæmic. Influenza has the history of an epidemic, and a short course. Tubercular meningitis has more severe and persistent vomiting, an abdomen that is not prominent, a lower temperature and slower pulse, and a delirium which appears later in the course. Acute tuberculosis may present identical symptoms with typhoid without the roseola. Gastro-enteritis also may simulate typhoid so closely as to be indistinguishable from it; here the presence of other cases of typhoid is of decisive importance.

Treatment.—The essentials of treatment are: 1, rest in bed; 2, liquid diet; 3, alcohol when necessary; 4, antipyretic treatment when necessary; prophylactic and symptomatic treatment are also to be considered.

1. Rest should be as complete as possible throughout the fever, and for at least ten days after the evening temperature has reached normal. Absolute confinement to bed with use of the bed-pan cannot of course be enforced with the youngest children.

2. The diet should be liquid, but may well be varied; milk always diluted with seltzer or lime-water, beef-tea, liquid peptonoids, egg-water, kumyss, matzoön, strained mutton, chicken, and oyster broths, are all useful in delicate children, and it is essential to have a nurse who can coax the child to take sufficient food when he rebels against everything. The amount and character of the nourishment should be rigidly prescribed, and the amount taken carefully noted. Liquid diet should be continued a week after the fever has departed, and as with adults the return to solid food be most gradual and guarded.

3. Alcohol should not be given till required, and the time of beginning need is probably best determined by a constant watch over the heart; any weakening of the first sound should be met by small amounts of wine, milk punch, or wine whey, and alcohol in some form is usually necessary during the second week. Marked nervous symptoms, as tremor, delirium, and stupor, also call for alcohol. The amount necessary varies usually from an ounce and a half of such wine as sherry, to four or six ounces of brandy, in the twenty-four hours.

4. Antipyretic treatment includes the use of water and drugs. Water may be applied as tub-baths, packs, sponge-baths, compresses, and cold enemata. Frequent tub-baths are not usually borne well by children ; collapse is more frequent with them than with adults. When they are used the temperature at the start should be 100° F., and he gradually lowered to 80° F. The bath should not last longer than ten minutes, and had best not be given oftener than twice daily. Sponge-baths and packs, however, may be given somewhat more frequently, and are distinctly helpful in quieting the child and making it comfortable. Iced-water bags, compresses, and enemata of three or four ounces, are comforting but not especially useful to lower temperature. Of drugs, quinine in large doses, sodium salicylate, antipyrine, acetanilide, thallin, and phenacetine are all recommended, and phenacetine in particular is widely approved as safe and reasonably efficient. It may be given in two- or three-grain doses to a six-year-old child.

Safety for others demands that in all dirrrhœal diseases the stools, diapers, and bed clothing stained by dejecta should be subjected to antiseptic treatment. Chloride of lime and carbolic solutions are customarily employed to disinfect stools, and clothing is boiled. The buttocks and anal region should also be regularly cleaned with an antiseptic solution.

For restlessness and insomnia, chloral hydrate, one-half to two grains, is usually efficient. Constipation should be avoided by glycerine enemata or suppositories. Diarrhœa may be checked by starch and opium enemata or by Dover's powder by the mouth. Headache may be relieved by local applications or by small doses of phenacetine. Griping pains may be met by the administration of hyoscyamine in quarter-milligram doses (Chauteaud granules). Otorrhœa may often be avoided by keeping the naso-pharynx well cleansed. A belly band forms a useful part of the treatment. *John H. Huddleston.*

TYPHUS FEVER. Typhus fever is not indigenous to the United States, and the few epidemics of which we have record are all directly traceable to importation from Europe. The reports of Dr. R. Robertson, a surgeon in the English navy during the War of the Revolution, show that, in 1776, the fever prevailed among the British and American sailors in the naval hospitals at New York and Newport, but it apparently never spread to the townspeople nor to the armies operating on shore. Nathan Smith, writing in 1824, states that he saw "typhous" fever as early as 1787, in New Hampshire ; but it is evident from his description that it was typhoid fever, and not typhus fever as now recognized.

The first well-authenticated outbreak of the disease was in the year 1807, at Hartford, and two or three other points in New England. The fever was epidemic in Philadelphia in 1812, and again in 1836. It was in the latter year that Gerhard made the observations which have had a large share in establishing a correct idea of the disease. The first considerable epidemic in New York was in 1847, following the Irish famine of that year. In 1861 the disease was again introduced here by Irish immigrants, and did not finally disappear until three years had elapsed. Since that time it has been twice mildly epidemic in this city—in 1881, and again in February of the present year. In all these cases the fever was brought to this country by immigrants from regions where it is endemic. It is an interesting fact that the disease has never become endemic here, but has always disappeared when suitable hygienic measures have been brought to bear upon it. It is believed to be always present in Ireland, Russia, Poland, and Bohemia. This endemicity has been attributed to certain characteristics of the races in those countries, which serve to perpetuate the germ. But we have many thousands of those races here, and yet the disease never breaks out among them spontaneously, nor do they show an especial susceptibility to the imported contagion. In the recent epidemic, indeed, the mortality was much heavier among the Americans who acquired the disease than among the Russian Hebrews who brought it with them. The fact that typhus fever was not introduced into America until comparatively recent years, has probably much to do with our exemption from its ravages. Had the immigrants of the last century been infected with the disease, it might well have obtained a firm foothold among us. But modern sanitation has taught us how to fight such diseases, and it now requires but a comparatively short time to get them under control, provided they are recognized before they have spread too widely.

I have given the above brief historical sketch of typhus fever in this country, as Dr. Chapin did not deal with this aspect of the subject in his article in Volume II. of the REFERENCE HANDBOOK. Dr. Chapin wrote in 1887, and his accurate and thorough description of the disease calls for no modification except in the one point of etiology. During the past five years several important studies of the etiology of typhus fever have been made by different observers. Llava,[1] in Bohemia ; Thoinot[2] and Calmette, in France ; Lewaschew,[3] in Russia ; and Cheesman,[4] in this country, have made careful and extended bacteriological investigations of the disease. These researches were carried on independently of each other, and the results, though not contradictory, are in no sense confirmatory of each other. Each observer made a morphological and biological study of the blood of the cases under his observation.

One or more organisms were found by all, but, as intimated above, these organisms were not the same in all cases. In spite of this lack of harmony in their results, it seems well to make somewhat extended mention of their experiments, as they represent the first efforts made in the way of the bacteriological study of typhus fever.

Llava, in the course of an epidemic of typhus fever in Prague, in 1888, examined the blood and viscera of thirty-three cadavers, as well as the blood of ten cases during life. A bacillus was isolated from the blood of twenty of the cases which had died, and from two of the living patients. This bacillus differed from any known form. Llava described it as an ovoid coccus or a very short bacillus, growing in pairs and in chains. From the latter growth-character, he termed it a strepto-bacillus. Its diameter varied from 0.9 μ to 1.2 μ, its length was about 1.8 μ, while the terminal individuals of the chains grew to the length of 2 to 3 μ. It developed rapidly in broth at a temperature of 37° C., forming chains, and was without visible spores. Platings and sowings were made in glycerine, agar, potato, gelatine, human blood-serum, and human and veal broth. No growth was obtained in gelatine or potato. Plated in agar, the colonies were circular or oval, lace-like, and whitish, with an opaque centre and transparent edges. The diameter of the largest colonies did not exceed 2 mm., and when magnified about one hundred diameters they appeared granular and showed very fine threads on their borders. The growth on human blood-serum presented the same characters. Human and veal broth showed a rapid growth, which settled in the form of a white precipitate, while the fluid above remained clear. The bacilli died in eight days in broth, and in twelve to fourteen days in agar. They stained with all the aniline dyes and by Gram's method. Culture inoculations of the strepto-bacillus were made in rabbits, guinea-pigs, dogs, cats, mice, and pigeons, with negative results. Inoculations in two young pigs gave more positive symptoms. In one case the temperature rose to 41.4° C. on the eighth day, and for sixteen days remained above 39° C. On the fifth day small reddish spots appeared on the skin, and disappeared after three days. In the other case no spots appeared. Loss of appetite and emaciation were marked in both cases. The animals were killed, and on autopsy showed degeneration of the kidneys and enlargement of the spleen. The

bacilli were not found in the blood or spleen, but were found in the kidneys of one case, and in an area of broncho-pneumonia in the injected lung of the other. Virulence of the cultures for young pigs was lost after a short time.

Thoinot and Calmette made a microscopical and bacteriological study of the blood of six cases of typhus fever during an epidemic of the disease on the Island of Tudy, in the spring of 1891. Five of the cases were under observation during life. In the sixth case the blood was taken from the heart and spleen about three hours after death. Platings and sowings were made from the blood of all these cases, but no growth was obtained. Inoculations were also made in rabbits, guinea-pigs, and pigeons, with negative results. The only positive results were obtained by the microscopic examination of the blood soon after it was taken from the body. The blood obtained by spleen puncture during life, and from the heart and spleen after death, gave the same results in all cases, namely, marked leucocytosis and the constant presence of small refracting granules, 1 to 2 μ in diameter, usually provided with short, thread-like prolongations. Sometimes the prolongations or filaments terminated in a little swelling. These minute organisms were in constant rapid movement among the blood-cells. After twelve to twenty-four hours, the granules were no longer seen, but only the long filaments. After forty-eight hours, neither granules nor filaments were to be seen. Thoinot and Calmette consider these organisms as specific elements, though they resemble forms seen in various other diseases, such as relapsing fever, pneumonia, typhoid fever, diphtheria, and erysipelas.

Lewaschew had opportunity, during the winter of 1891–1892, to observe many cases of typhus fever in Casan, Russia. He took the blood from the finger and spleen during life, and studied it microscopically and bacteriologically. In the fresh blood he found peculiar small, round, strongly refracting bodies which were constantly in active movement. The longer the blood had left the body, the slower became the movements, until finally they stopped entirely. Sometimes these bodies were completely black and filled with minute granules of black pigment, probably—in Lewaschew's opinion—blood-coloring matter. On careful study, it appeared that these bodies were provided with slender, thread-like prolongations, the latter also in constant motion. These thread-like bodies were also seen detached from the round bodies. Lewaschew considers that the cocci, the cocci with thread-like attachments, and the free motile threads, are all forms of the same micro-organism. The number of these minute organisms varied greatly. Few in number at the beginning of the disease, they increased rapidly during its farther development, and diminished as the temperature declined. These organisms were not so numerous in the finger-blood as in that obtained by spleen puncture, nor were they so constantly present. Lewaschew also obtained positive results from his cultures of typhus blood. As typhus fever does not develop in animals, he decided to use human serum for his culture medium. He made use of the fluid of ascites taken from several patients. Characteristic cultures were obtained in from twenty-four to forty-eight hours, at a temperature of 36° to 37° C. They remained sterile at room temperature. The growth was most rapid in one per cent. serum agar, very poor in one and a half per cent.

The cultures showed at the place of puncture a small grayish-white cloud, which at first was usually half transparent. The shape was sometimes round, of the size of a small hazel-nut; in other cases of the same size, but cylindrical in shape. This size was attained in the first days after sowing, there being no increase later. The cultures only grew in the lower part of the agar, and never in the upper layers. Cultures were obtained both from finger and spleen blood. The microscope showed the colonies to be composed of a pure culture of minute cocci of the size of 2 to 5 μ. The cocci were generally separate, occasionally in pairs, and still more seldom in small chains. They were usually in active motion. Some were seen to have slender prolongations, with a length equal to six or eight times the diameter of the cocci. These thread-like tails were also in constant motion, resembling the spirillum of relapsing fever. The cocci are held by Lewaschew to be a specific micro-organism, micrococcus exanthematicus, or coccospirillum when provided with tail resembling the spirillum. The bacteriological findings thus confirmed the results of direct examination of the blood. In the latter a magnifying power of from 1,000 to 2,500 diameters was used. The cocci were present in the blood from the beginning of the disease until shortly before the end. They sometimes changed during the course of disease, the body of the coccus becoming larger and the thread-like attachments thickened, so as to be evident to the eye under a lower power. Sometimes the prolongations lost their even, regular shape, and showed one or more thickenings at different points, some even as large as the coccus itself. The movements were still energetic in all directions. If the blood is observed for several hours, the movements of the prolongations gradually cease, and it finally falls into granules. It is difficult to identify the tail in dry, stained preparations, as it is so delicate in structure.

Cheesman's investigations were made during the recent outbreak of typhus fever in New York City. He made a morphological and biological study of the viscera from three cadavers, and of the blood obtained by finger-puncture from six living patients, during the height of the disease. Platings and sowings were made from the viscera of the three cadavers, but with negative results. The platings were made on beef blood-serum and on six per cent. glycerine agar, in Petri dishes, and in Blücher's anaërobic plates. The sowings were in beef blood-serum, both fluid and coagulated, in sealed and unsealed tubes; in beef-broth and glycerine agar tubes; by deep puncture in alkaline agar tubes, and in Nikiforoff's anaërobic tubes, charged with six per cent. glycerine beef-broth. All of these cultures were kept at 37.5° C., and were studied daily for sixteen days, many of the tubes for a much longer period. In no case was there any growth, except some scattering later contaminations on the plates. Sections of the spleen, liver, and kidney from these cases were stained by Gram's method, and examined under a one-sixteenth oil immersion lens for any micro-organism which might be present, but none were found. The blood, obtained by finger-puncture under the usual antiseptic precautions from the six living patients, was streaked on six per cent. glycerine agar plates and smeared on sterilized cover-glasses. The cover-glass preparations were dried in the air, fixed in alcohol, and stained in Czenzynski's solution for eighteen hours, at room temperature. Careful examination with the immersion-lens showed a few blue-stained bacilli on about one-half of the cover-glasses, never more than eight or ten on a cover. In length they were usually about one-sixth of the diameter of a red blood-cell. They were round-ended, and were usually found singly, lying apart from the blood-cells, but in a few cases groups of from three to six bacilli were seen. The platings, made from the blood of six patients, were kept at 37.5° C., and showed a growth of colonies in from two to four days. The number of colonies varied on the different plates, from sixty or seventy in one case to a single colony in another case. These colonies, though thus varying in numbers in all of the six cases, presented the same general appearance. Cover-glass preparations showed that the colonies were formed of small bacilli, and subsequent morphological and biological study proved them to be identical in all the different cases. The diameter of the bacillus varied from 0.5 μ to 0.8 μ, and the length from 1.0 μ to 2.5 μ. It occurred singly and in pairs, rarely in chains of six or eight. It was often club-shaped, and was found to be ovoidal in young cultures. It stained readily with the ordinary aniline dyes, and retained the color after staining by Gram's method. Under the most favorable circumstances growth was not voluminous. The most abundant growth obtained was on beef blood-serum at 37.5° C. The colonies growing on

six per cent, glycerine agar plates presented to the naked eye, in about eighteen hours, in oblique light, a scanty growth, consisting of minute bluish-gray translucent spots. Older colonies appeared dry and scaly to the naked eye, were flat, whiter, and more opaque, and never exceeded 2 mm. in diameter. When examined under a hand magnifying-glass, they showed a central thickening. When magnified about 100 diameters, the surface appeared coarsely granular and the edge was formed of short, coarse, irregular spiculæ. Glycerine agar tubes at 37.5° C., showed the same surface growth appearances as the plates. In the line of puncture small, white, isolated colonies occurred, and in the condensation water there was a white deposit, quite perceptible in twenty-four hours, the fluid above remaining clear. On coagulated beef blood-serum, at 37.5° C., the growth is slightly elevated, white, and shiny. In beef broth the growth is slight, and settles in the form of a white precipitate, the fluid above remaining clear. In milk the growth appears as a white deposit; the milk itself undergoes no apparent change. No visible growth was obtained on potato or on macaroni. Inoculations of broth-culture were made in eight rabbits, two guinea-pigs, and two white mice. All the animals showed marked emaciation, and with the exception of two rabbits, all the animals experimented upon died in fourteen to twenty-nine days. The inoculated bacillus was recovered from the heart's-blood of two of the rabbits that died. The bacillus found by Cheesman bears considerable resemblance biologically to the "strepto-bacillus" of Llava; morphologically it differs, being somewhat smaller and showing but very slight tendency to the formation of chains. A striking difference is also shown in the effect of its inoculation in animals. Cheesman himself does not believe this bacillus, for which he suggests the name of bacillus sanguinis typhi, to be identical with the strepto-bacillus described by Llava. Cheesman concludes his paper as follows: "The fact of finding a new species of bacillus in the blood of six consecutive patients, with uncomplicated typhus fever, in the height of the disease, seems significant, and is suggestive of an etiological relationship of the bacillus found to the disease. This relationship cannot be determined by a single limited research. The proof must be furnished by an accumulation of evidence, either along lines such as have been pursued in this investigation, or in directions which may present themselves as our knowledge increases."

ULCERS. The treatment of ulcers has been somewhat altered by the topical use of the newly introduced chemicals and by newly suggested or revived methods of dressing. Of the more recently introduced antiseptics we must mention peroxide of hydrogen, the aniline dyes (pyoktanin, methyl-violet, malachite-green, etc.), and aristol. Peroxide of hydrogen is especially indicated in foul sloughing sores, and should be applied in full strength directly to the surface of the ulcer until effervescence ceases, when one of the ordinary wet dressings can be applied. The aniline dyes are employed in tolerably strong (ten per cent.) solutions, or a gauze prepared with them may be used. They are good absorbents, and appear to exercise a certain astringent and perhaps stimulating effect upon the ulcer. Aristol is antiseptic and stimulating, but its cost will prevent its common use.

Dermatol is another newly introduced chemical, said to be a sub-gallate of bismuth. It has been recommended as an odorless substitute for iodoform, but its antiseptic qualities are of the feeblest. It is, however, an excellent astringent application for ulcers when used in the form of a powder, and will cure many which resist other applications. Strict antiseptic precautions should be observed in treating ulcers with it, as the writer has known of a case in which erysipelas developed in a granulating surface dressed daily with this powder.

Massage has been successfully employed in the treatment of ulcers of the chronic variety, and is an excellent adjuvant to other methods of treatment, as it disposes of the œdema and thickening and induration about the ulcers, and so places them in a condition more favorable for healing. But before massage can be used, the ulcer and its surroundings must first be made perfectly aseptic by thorough cleansing, and shaving if necessary, followed by the continuous application of antiseptic dressings for some days beforehand, otherwise septic infection of the glands and even of the entire system might follow. When asepsis has been secured the surroundings of the ulcer are massaged, using lanolin as the emollient, and beginning with very light strokes—"effleurage" (Appenrodt, *Wiener med. Wochenschr.*, 1888, p. 1010; and *Deutsche med. Wochenschr.*, 1888, p. 478). Even the surface of the ulcer can be subjected to the massage by protecting it with a few layers of gauze and operating through them, thus reaching the induration so frequently found at the base of the sore.

As early as Sir Everard Home's time (1797) lead plates were applied to the surfaces of ulcers, and a recent revival of the idea is seen in the use of tin plates, as suggested by Moras (*Medical News*, Philadelphia, 1890, lvii., p. 626) and others. A piece of ordinary sheet-tin is cut to fit the shape of the ulcer and large enough to project one-quarter of an inch beyond it on all sides, and the edges are turned back a little so as not to cut into the skin. The tin plate is then covered on the side next to the ulcer with rubber tissue, and secured upon the sore by strips of adhesive plaster, so as to make firm and even pressure. An absorbent dressing of gauze, or of gauze and cotton, is applied over this with a bandage. The parts should be thoroughly cleansed before applying the tin, and the outer dressing must be changed frequently if the discharge is profuse. As the ulcer heals, the plate should be cut smaller. Good results have followed the use of this method in some cases upon which it was tried under the observation of the writer.

The principles of asepsis and occlusion are followed in a method of dressing ulcers recently highly recommended by Morton (*Times and Register*, Philadelphia, 1892, xxiv., p. 672), and resembling that advocated by the writer in the main work, but he does not lay sufficient stress upon infrequent dressing—that is, rest for the sore. In a dressing made with Unna's oxide of zinc gelatine, reported by Heidenhain, the idea of rest and occlusion is well carried out (*Berliner klin. Wochenschr.*, 1892, p. 323). The leg is given a very thorough washing with soft soap for twenty or thirty minutes and is then well scrubbed, even over the ulcer and any eczematous spots which may be present, with a 1 to 1,000 bichloride of mercury solution. Iodoform, dermatol, or any other topical application is applied to the surface of the ulcer, and then the entire leg is painted with the oxide of zinc gelatine, rendered fluid by standing the pot containing it in warm water, and applied with a stiff brush. A starched (crinoline) bandage is then applied smoothly over this layer from the toes to the knee, and is in turn painted until four layers of gelatine and starched bandage have thus been laid on alternately. An ordinary bandage is applied outside of all, and in fifteen minutes the patient can be allowed to walk. The dressing is changed twice a week at first, later only once, and finally it can be worn for five or six weeks without renewal.

It is important to emphasize the fact that when skin-grafting has been employed for chronic ulcers of the leg, prolonged and careful after-treatment is necessary, else the poor circulation in the extremity will cause the new skin to fail, and disappointment will result. Various observers have reported as many as fifty per cent. of failures in these cases. To avoid such poor results, stringent precautions are necessary, and Urban thus describes the preparatory and after-treatment of these cases in Thiersch's own clinic (*Deutsche Zeitschrift für Chirurgie*, xxxiv., p. 187): "Whoever wishes to undertake successfully the healing of large ulcers of the leg must,

in order to be sure of his ground, demand in the first instance a course of treatment lasting from three to four months, that is, six to eight weeks for the preparation of the ulcer, and the same time for healing after transplantation. During the entire time the patient remains in bed. . . . The patient receives a warm bath for the leg twice daily, from the beginning of treatment. The dressing is a compressive dressing with a non-irritating fluid, generally Thiersch solution (Ac. salicyl., 1 ; ac. boric., 6 ; aquæ, 300 parts). . . . When the surface has become clean, and all sloughs have separated, and the granulations are growing in a healthy manner, the latter are cauterized twice a week with nitrate of silver. The rest of the treatment remains the same—a bath and compressive dressing applied twice a day. This treatment is continued until all signs of inflammation have disappeared from the surroundings of the ulcer, cicatrization is proceeding on the edges, and the granulations are firm and secrete little pus. Finally the surgeon may attempt to reduce the thick cicatricial infiltration in the neighborhood by gentle massage or by the use of the rubber bandage. After this preparatory treatment has lasted six to eight weeks, according to circumstances, the skin-transplantation is carried out strictly according to rule. . . . Reckoning from the day of skin-transplantation, the patient must submit to at least six weeks of continuous rest in bed. While the patient may be allowed to get up to go to stool during the preparatory period, the stools must now be had with the aid of the bed-pan, lying down. . . . After four weeks he may be lifted into the bath, but standing up, or the assumption of the erect position in any way, must be carefully avoided. . . . Six weeks after the operation the patient is allowed out of bed for the first time. A flannel bandage is firmly and carefully applied beforehand, from the toes to the middle of the thigh. From that day on, he spends a little longer time out of bed every day, and in a few days begins to walk. . . . Even for small ulcers of the leg due to varicose veins, the patients must under no circumstances leave the bed before four weeks after the operation. After completing the course of treatment, the patients are directed to bandage the leg properly every morning for some months.

Keating (*Lancet*, 1890, i., 231) has described a method of amputation for cases of ulcer, a very rare operation in modern surgery. He takes a flap from the sole or the dorsum of the foot, according to the situation of the ulcer, or even from both in ulcers surrounding the limb, and by using these flaps to cover the denuded surfaces a much longer stump can be obtained than by the ordinary methods. But we must refer to the original paper for details and diagrams explaining the technique.

B. Farquhar Curtis.

URAL. URALIUM. This drug is also known as chloral-urethane, and, as its name implies, is a compound of urethane and chloral. Chloral at ordinary temperatures, or melted chloral-hydrate, dissolves urethane ; this product, treated with hydrochloric acid and sulphuric acid, produces an oily liquid, which subsequently crystalizes and forms this new compound. It occurs as a white crystalline body, readily soluble in alcohol, but almost insoluble in water. It is decomposed by hot water.

Ural was introduced by Dr. Poppi, of Bologna, as a better hypnotic for neurotic patients and the insane than most of the drugs employed for this purpose. He considered it to be more active than urethane and more safe than chloral, and better borne by the stomach. It does not exert any action on the heart or influence blood-pressure. He had employed it in a large number of cases of insomnia, in inebriates, in phthisis, and in heart and nerve diseases, in doses of from thirty to forty-five grains, with an almost invariable good result.

In the hands of others it has not furnished such favorable results, and has not secured any position as an hypnotic remedy. Drs. Schmitt and Parisot, of Nancy, tested the drug in a variety of cases with very little satisfaction. They administered it in alcoholic solution, and found that the smallest dose capable of producing any effect was fifteen grains, but doses of even thirty-eight grains were by no means always successful. It also proved very disagreable to take and disturbed the digestion, sometimes causing vomiting, followed by nausea. In some cases vertigo was complained of. As a result of their researches they arrived at the following conclusions : 1. Ural, like chloral, is a soporific. 2. According to the dose employed, a profound sleep is produced, accompanied with anæsthesia, abolition of the reflexes, slowing of the respiration and pulse, depression of the temperature, and lowering of the arterial pressure. 3. Toxic doses produce death by respiratory failure, the heart being arrested in diastole. 4. Like chloral, it acts successively on the cerebrum, the medulla, and the spinal cord. 5. Ural has no advantage over chloral, and has the inconvenience of being insoluble in water.

Beaumont Small.

URETHANE. This hypnotic has not proved a very serviceable drug, and is gradually falling into disuse. Many observers, however, are very pleased with its action and place great reliance upon it in cases where the more powerful and active hypnotics cannot be employed. The chief objection to its use is the uncertainty of its action. In health it has no soporific effect, and, in the insomnia of disease and in mental disorders it very frequently fails to produce the desired effect, and, in many cases in which sleep has followed its administration, it has only lasted for a short time. A rapid tolerance of the drug has also been noticed. In numerous instances, where full doses have produced several hours of tranquil sleep, the continued use, even in larger doses, has failed to exert any hypnotic action. It is to be valued as a mild but very safe hypnotic in simple cases of insomnia in persons of a nervous temperament, and in cases of melancholia. It is also recommended as a very safe drug in the insomnia of cardiac troubles, particularly aortic insufficiency. In the diseases of children it is particularly suitable. The sleep which is produced by urethane is always pleasant and tranquil. The patient awakes without any confusion of ideas, dizziness, or headache. The only unfavorable effect produced by its employment is a derangement of the digestive organs, but in occasional and moderate doses this is not noticed to any extent.

The safety of urethane has led to combinations with chloral, which are supposed to be more efficient and safer than either of the component drugs when administered separately. See Somnal and Ural.

The dose of urethane must not be less than from thirty to sixty grains, which may be given in watery solutions flavored with peppermint, cinnamon, bitter orange, or any aromatic.

Beaumont Small.

UTERUS, CARCINOMA AND FIBROID TUMORS OF THE. I. Carcinoma.—Recent development in the pathology of carcinoma or cancer of the uterus makes it desirable to drop the names scirrhus, colloid, and medullary, as tending to confusion. They are neither scientific, nor distinctive. As adjectives descriptive of the appearance of a given specimen they might be convenient, but as generic terms they are inadmissible.

Cancer of the Body of the Uterus.—From a clinical as well as an anatomical standpoint, we may separate these cancers into corporeal and cervical.

Corporeal carcinoma is met with in two varieties : the glandular cancer, or adeno-carcinoma corporis ; and the cancer of the mucous membrane, or epithelioma corporis. Again, this latter variety may occur in a circumscribed and in a diffuse form.

The adeno-carcinoma is the development of cancer upon a glandular endometritis. By unlimited proliferation the columnar epithelial cells fill the glandular tubules instead of merely lining them, while the tubules themselves expand at the expense of the surrounding connective tissue. Some, becoming contorted, divide up, press against and communicate with neighboring ones, while others maintain the form of distended tubes. The cells are multi-nucleated, enlarged, and become compressed

into various shapes. From this time on, the changes are identical with the primary cancer of the mucous membrane.

Diffuse epithelioma of the corpus uteri is characterized by an exuberant development of villi over the whole mucous membrane. The glandular tubules are more or less filled with cells, while some are stopped up and form cavities containing also some mucus. The abundance and large size of these cells, and the scarcity of the surrounding stroma, give the growth a soft medullary character. Fat-cells, pigment, and granular detritus are also found. The uterus is softened, enlarged, and filled to the internal os, but not beyond it. In the later stages, however, the cervix becomes invaded, and nodules appear in the uterine walls and surrounding lymphatics. The diseased action respects no longer any barriers.

Circumscribed epithelioma of the corpus uteri exhibits about the same histological features as the variety just mentioned, but projects from only a limited portion of the endometrium. After a time the cancerous changes invade the uterine parenchyma, and progress with about equal rapidity in all directions, not hesitating to pass straight through to the serous surface.

Some authors claim that the disease may commence in the form of cancerous nodules, developed primarily in the connective tissue of the uterine walls, as occurs in the cervix.

The characteristics of all these growths, as of all cancers, consist in an exuberant atypical growth of epithelial cells within a fibrous stroma of small alveoli. This stroma contains the nutrient blood-vessels, until nutrition is cut off by the over-accumulation of cells, and necrosis results. Encapsulation never occurs. But all this does not establish the disease, unless coupled with the power of invading contiguous tissues.

For a time, corporeal epithelioma also respects the internal os, but finally invades the cervical walls, reaches the peritoneal surfaces, and causes agglutination and fixation of the uterus to the bladder, rectum, and upper bowels. The uterus does not always enlarge greatly, for necrosis and excavation take place, limiting the growth, and opening into the surrounding viscera. Thus a large cavity may be created, which is the common receptacle of urine, fæces, and the horribly fetid ichor and detritus which come from the cancer.

Etiology. — This disease would seem to be closely connected with degenerative changes in the uterus, such as attend the menopause. But few cases occur before forty, and the majority have been observed in women at and beyond fifty. Nullipara are not infrequently attacked. That endometritis remaining uncured at the change of life is more difficult of cure than earlier, is a significant fact.

Malignant disease of the uterine body occurring before the age of forty is usually found to be sarcoma. In young people, the tendency to the development of an excess of connective tissue in the diseased uterus may possibly be the factor determining toward sarcoma. However, there is still much to be learned and unlearned with regard to the malignant diseases. Whether a microbe is necessary to their development is an open question, and will probably so remain until inoculation experiments have been made upon diseased (not healthy) tissue. Negroes are said to suffer less from corporeal and cervical cancer than whites, but I have seen so many cases among negroes that I am led to doubt it.

The disease is not, strictly speaking, hereditary, although it is possible that a susceptibility to it may be.

Diagnosis.—The diagnosis of cancer of the body of the uterus, while easy in the advanced stages, is often exceedingly difficult at or near the onset of the disease. The enlarged and softened uterus, the repeated hæmorrhages between the menstrual periods (or after their cessation for months or years), the abundant ichorous and foul-smelling discharges, recurring pains of a cramping character in the lower abdomen, pelvic infiltration, and anæmia, all go to make up a constellation of symptoms easily recognized. If the finger can be pushed into the softened cervix, and the soft pultaceous or friable mass felt, the diagnosis, if not already certain, can be made so by microscopical examination of removed tissue.

A sloughing, intra-uterine fibroid, or one with a sloughing capsule, may present itself at the os and simulate cancer, but the chronicity of the symptoms of pain and hæmorrhage, and absence of infiltration of the uterine walls, together with the microscopical examination, will remove all doubt. These conditions are seldom found after the menopause, unless the symptoms of the disease have dated back to, or before, the menopause, while there is usually no continuity of the signs and symptoms of uterine cancer and those previously noticed during the menopause.

Before the disease has become so pronounced it may often be differentiated from chronic disease of the uterus and appendages, in old people, by the fact that the symptoms come on after a long period of immunity from pelvic disturbance. In cases of senile metrorrhagia, leucorrhœa, and pelvic pains, an almost uninterrupted connection between the former inflammation and the present symptoms may be traced. When old and long quiescent pelvic inflammatory disease assumes activity, anodynes, laxatives, fomentations, counter-irritation, and rest in bed, cause the inflammation to subside rapidly. A local examination will often discover more disease in the uterine appendages than in the uterus itself. Cancer of the uterus progresses steadily and rapidly, and is therefore never a very old affection.

Most important, however, is the diagnosis of the disease in its incipiency, when a radical cure is possible. Metrorrhagia, beginning many months or years after the menopause, usually indicates cancer, and always calls for a local examination. If no cause outside of the uterus be found, the uterus should be curetted and the removed particles examined. Usually there will be some enlargement or softening of the uterus, a musty or perhaps cadaverous odor, and some irregular projections from the endometrium as felt by the probe or penetrating finger.

In all cases of metrorrhagia in patients over forty years old, in whom this or other symptoms belonging to carcinoma rapidly assume an active character without discoverable cause, the uterus should be thoroughly curetted. The case should be carefully watched afterward, even if the microscopic examination prove negative. In old people the uterus has several times been taken out for the symptoms of persistent hæmorrhage after curetting, and the cancerous nature of the disease discovered then only.

The presence of large inguinal glands denotes an advanced stage of the disease; and if accompanied by deep-seated lumps in the iliac region with pain and lameness in the limb of the same side, indicates that a fatal termination is not far off. Uterine hæmorrhage and general weakness do not always allow the local disease to progress thus far. Infiltration of the pelvic connective tissue first occurs in the form of nodules in the broad ligaments in corporeal carcinoma, and in the sacro-uterine and bases of the broad ligaments in the cervical disease. They are detected by a rectal examination.

We should be on the lookout for early symptoms, for a late diagnosis is all but valueless to the patient. It should also be remembered that glandular endometritis may exist as such for a time and finally undergo malignant transformation.

Treatment—Curetting, and the intra-uterine application of styptics, such as the liquor ferri perchloridi fortior, are palliative, and should only be employed preparatory to a radical operation, or after the time for such operation has passed.

The only real treatment is a hysterectomy, and usually, a total extirpation per vaginam. If the diagnosis were made early, such an operation would yield a mortality of less than five per cent. in the hands of the experienced gynecological surgeon, and the permanent cures would not be infrequent; for all diseased tissue would be removed, and with it the danger of a recurrence.

Vaginal hysterectomy is a comparatively simple opera-

tion, fully as easily performed as high amputation of the cervix, and almost as safely. The steps are as follows: After a thorough disinfection of the parts, the cervix is drawn down by vulsella or sutures, and incision is made two-thirds around the cervix, from one-third to one-half inch from it, anteriorly and laterally. The bladder is separated from the uterus by the finger or knife handle until the peritoneal cavity is entered, and the peritoneal opening is enlarged laterally with the fingers. The incision around the cervix is then completed, and the recto-uterine pouch opened close behind the cervix, and the opening enlarged laterally with the fingers as far as the sacro-uterine ligaments. Now the left forefinger is carried behind the attachment of the left sacro-uterine ligament, and the thumb in front of the broad ligament, and a ligature carried through the connective tissue as far from the cervix as practicable, so as to include a portion of the bases of each, and tied. Then the remainder of the sacro-uterine and the base of the broad ligament are similarly ligatured, and the ligatured tissues cut through close to the cervix. The manœuvres are now repeated on the other side, and the cervix is loosed so that it can be drawn down outside the vulva, and the remaining portions of the ligaments ligatured in one, two, or three parts according to their size, and the uterus cut out. Bleeding from the raw connective tissue or vaginal edges may be controlled by sewing the vaginal and peritoneal edges together with catgut. Give extra attention to bleeding vessels under the sacro-uterine ligaments.

Adhesions or indurations may diminish the elasticity of the connective tissue, so that even after the cervix is liberated, the uterus cannot be pulled down. In such cases we may have to place forceps upon the remaining portions of the broad ligaments, one on each side. Occasionally, the vagina will be narrow, and the pelvic connective tissue so rigid that we cannot get the cervix down well enough to apply the ligatures firmly and safely. In such cases we can apply a pair of large hæmostatic forceps to the bases of the ligaments on each side, and another pair to the upper portion. Bleeding from the smaller arteries about the vaginal edges is then controlled by small forceps.

A strip of iodoform gauze two inches wide should be tucked into the vagina as far as the stumps, but it should not project up between the intestines.

The small forceps should be taken off in twenty-four hours, those on the broad ligament in forty-eight hours. The ligatures or sloughs from the forceps come away in about two weeks.

Vaginal hysterectomy has proved to be so safe an operation, that some have advocated its performance even after a nodule or two can be felt in the connective tissue by rectal indigitation—these glands being enucleated if possible. This might prolong the patient's life for a year or so, and should be considered seriously before she is turned away.

II. Fibroid Tumors.—One of the characteristic triumphs of the last decade has been the improvement made in the treatment of uterine fibroid tumors.

In order to better comprehend the therapeutics of these growths we will make a clinical division into five main varieties, viz.: (1) The fibroma uteri, composed largely of connective tissue, and with a well-defined capsule; (2) the myoma uteri, composed mainly of muscular tissue, and without any well-defined capsule; (3) the fibro-cystoma, or a fibroma containing, or connected with, one or more cavities of fluid; (4) the œdematous, or soft fibroma, which is a fibroma infiltrated with fluid; (5) the myo-cystoma, or sac of fluid contained in the greatly enlarged uterine wall. These tumors may undergo fatty, calcareous, sarcomatous, myxomatous, septic, or gangrenous degeneration.

The myoma contains connective tissue, but in small quantity as compared with the fibroma, which in turn contains muscular tissue in comparatively small quantity. The fibromas are found much more frequently than all the other varieties together. They may occur as large numbers of small or moderate-sized nodules, either grouped together or scattered throughout the uterus, or as large single masses. The myo-cystoma is a round cyst projecting from the uterus, and covered usually by quite a thick layer of muscular tissue. Smaller cysts with thin septa sometimes project into the main cyst. The uterine body is somewhat enlarged. They are undoubtedly the result of early complete cystic degeneration of fibromas, leaving nothing but cysts surrounded by the myomatous tissue of the uterine walls. They grow rapidly. I removed one the size of a six months fœtus, that within eight months had grown from the size of a hen's egg. The teleangiectatic or cavernous fibroid is a rare growth, whose interior is traversed by large blood-sinuses.

Differential Diagnosis.—When large enough to extend above the pubes, the myoma, the myo-cystoma, and the single fibroma give rise to globular tumors that feel and appear, as far as the shape and position are concerned, like the pregnant uterus. They are, however, all harder, with outline more easily definable, can usually be felt to extend down into the pelvis in the median line just behind the pubes, and can be rocked a little from side to side. The myoma and myo-cystoma, and the œdematous fibroma, give an obscure sense of fluctuation, while the fibroma is hard. The multiple fibroma is hard, irregular in shape, often extending higher on one side than in the middle, usually less movable than the others, and dips into the pelvis on one or both sides, as well as in the median line. Large fibro-cystomas are apt to fill the lower abdomen, and fluctuate the same as ovarian tumors.

Vaginal indigitation in the cases of myoma, myo-cystoma, and single, intra-uterine, or submucous fibromas finds a similar shape as in the case of pregnancy, except that both cervix and tumor are harder. The bulging of the tumor may, however, commence low down, so as to leave but a very short cervix below it, or high up, so as to leave the uterus, at or just above the internal os, small. In pregnancy the bulging begins at the internal os, and feels softer. These tumors may cause the bulging to be a little greater on one side than on the other. Fibromas developed near or at the external layers of the lateral uterine walls first bulge to one side, then push the cervix in a direction opposite to their growth, usually toward the opposite groin, or a little more forward, and then lift the cervix up toward the pelvic brim. When tumors grow into both broad ligaments the cervix remains near the median line, usually somewhat forward, and, as it ascends, often gets somewhat behind the pubes. The uterus, on account of the tension of the broad ligaments, is quite immovable. Tumors in the uterine cavity, or in the anterior uterine wall, as they grow large, tip the fundus forward and the cervix backward, unless retroversion already exists.

The uterine cavity is much elongated in the polypoid submucous and intra-mural fibroma, but little in the subperitoneal and intra-ligamentous fibromas, and moderately, when at all, in the myomas and myo-cystomas.

Treatment.—Electrolysis has been revived by Apostoli, and has taken a place among the therapeutic agents used for the cure of fibroid tumors. For a while it was thought to symptomatically or practically cure the great majority of cases, and many went so far as to say that all tumors should be treated with electricity before being removed. But a reaction has set in. The failures are being discovered, and the imperfect character of the cure is being acknowledged, so that there is a danger of electrolysis losing the place it deserves.

In the first place, according to the experience of F. H. Martin, of Chicago (personal communication), electricity is useless in all cases of cystic fibroids and intra-uterine polypi. Subserous fibroids, particularly the multiple variety, are but little affected by it. This would leave it to be used in the myomas, which are rare tumors, and the interstitial and submucous fibromas, or a little more than half the cases. Its action on the hard tumors causes but little diminution in their size. A few of the small and softer fibroids are said to disappear after electrolysis. The most that is accomplished, however, in the most favorable cases of large tumors, is a cessation of the hæmorrhage and a slight diminution of their size. Often the growth is merely arrested.

Electrolysis may therefore be tried in all but the cystic, multiple, subperitoneal, and polypoid varieties, with the end in view not of curing them, but of arresting their growth, diminishing their vitality, curing the metrorrhagia, and thus rendering them harmless until the conditions attending the menopause shall supervene and aid in the process of retrograde metamorphosis. When, after a trial of a few months, electrolysis fails to check the growth or restrain the hæmorrhage, or if it increases the latter or the sensitiveness of the tumor, its use should be abandoned.

The true electrolytic action does not produce much effect, excepting upon the parts near the negative intra-uterine pole. The positive pole, however, may be used to cicatrize and contract the inner surface of the uterus, and thus diminish, to a certain extent, the vascularity and vitality of the tumors. Contractions of the uterus are also produced by the current, and may affect the vitality of the parts somewhat as ergot does, although less continuously.

The technique of uterine electrolysis need not be given here, for no one should undertake to use the method without a study of the subject in some work devoted especially to that purpose. The principle consists in using large volumes of galvanic electricity, and in its exact dosage. From fifty to three hundred miliampères are used with the aid of a milliampère-meter. One electrode should be introduced into the uterine cavity, and another placed on the abdomen. An insulated uterine sound, a large flat abdominal electrode, and other special appliances are needed. Electro-puncture is, I think, a dangerous procedure, and should be employed only by the specialist.

After the failure of other remedies to check the growth of a fibroid tumor, the knife should be promptly resorted to, unless the patient is very near the menopause. Delay may mean increase in size, adhesions, subperitoneal development, cystic or malignant degeneration, and consequently a much more dangerous operation. The mortality of abdominal section in cases properly chosen need not, at present, be over five per cent. In neglected cases it is about twenty per cent. Tumors not larger than the fist, when accompanied by menorrhagia, may be cured by an oöphorectomy, to bring on the menopause. Large tumors are not always helped by this operation. As a rule, a tumor should not be allowed to become as large as a six months pregnant uterus before being removed. When first brought to our notice at that size, we should watch them closely and treat them vigorously by ergot or electricity, and, if their growth is not soon arrested, operate before they become much larger.

Until within the last few years, it was generally the practice to wait until the tumor grew so large as to menace life, and then to operate. But few died of the disease, for most of them died of an operation done too late. Now we understand better how to select the cases that are not amenable to treatment, and operate before the tumor becomes too formidable. Abdominal hysterectomy has become so far perfected that we can operate upon such cases with a mortality on a par with that of ovariotomy.

Intra-uterine fibroid polypi should be removed as soon as discovered. Subperitoneal fibroid polypi should be removed when they become large enough to cause much inconvenience. All cystic fibroids should be removed as soon as diagnosed. Simple myomas and simple intramural fibromas in young people, should be treated with electricity and ergot; but if, after a long course of treatment, their growth is not checked, they or the ovaries should be removed. Rapidly growing fibromas, with many subperitoneal nodules, should be operated upon early if the treatment does not check their growth, for their numerous foci often cause them to grow very large and rapidly, and to assume such relationships as would early cause trouble, and render an operation difficult. Very slowly growing fibromas with numerous scattered nodules, may interfere with uterine circulation and nutrition, so as to lead to a cessation of their growth. As a rule, fibroids, excepting the cystic and intra-uterine polypoid, which are observed near the change of life, should be patiently treated with the hope that the menopause will cure them. Development in the broad ligaments forbids a long delay in operating.

Uncontrollable metrorrhagia, unbearable pains, rapid growth, often determine an operation. Occasionally it becomes necessary, on account of symptoms, to remove a fibroid when still small. In such cases, a vaginal hysterectomy is preferable to abdominal section, as being safer. The existence of polypi, whether projecting into the uterine cavity or into the peritoneal cavity, does not call for a hysterectomy. Sometimes, one or two subperitoneal fibroids may be enucleated, and the bed sewed up without sacrificing the uterus. The myxo-fibromata, fibro-sarcomata, septic and gangrenous fibroids, should be removed when discovered early enough.

Cervical fibromas are usually single and can be enucleated without danger. The bed should be sewed up or thoroughly packed to prevent hæmorrhage, for cervical tissue does not readily contract. When a cervical tumor projects up into the cul-de-sac of Douglas and gets quite large, a hysterectomy is occasionally required.

Henry T. Byford.

VACCINATION. In the article upon Vaccination presented in the seventh volume of the REFERENCE HANDBOOK, a brief history of the subject was given, together with such data relative to the prevalence of small-pox at different periods as the subject required, since a correct and thorough understanding of the value of vaccination cannot be had without a corresponding knowledge of the prevalence of small-pox, not only at different periods of time, before and after the introduction of vaccination, but also in different countries, under different degrees of legal enforcement and in the absence of all laws.

The Pre-vaccination Period.—The data relative to actual deaths from small-pox in the pre-vaccination period are meagre, but those which have been brought to light are of great value. The most valuable of these statistics have been published in the "Report of the British Parliamentary Commission on Vaccination, of 1871," and in those of the present commission, appointed in 1889, but still in session (1893). A portion of the former was quoted in the seventh volume of the REFERENCE HANDBOOK, pp. 223–234. In addition to the statistics of Geneva, mostly of the seventeenth and eighteenth centuries, and of the town of Kilmarnock, from 1728 to 1763, the following account of "Small-pox Mortality in Pudsey a Century Ago," is given by Dr. W. L. Hunter, *British Medical Journal* (1892). This brief history covers the period from 1777 to 1813 inclusive (thirty-seven years). The curate of Pudsey, Mr. Howarth, kept a careful record of burials, giving names, ages, sex, and as far as could be known, the cause of death. The record is incomplete, since it refers only to those who were buried in the chapel yard. Many other burials took place in other yards. The average population of the town was 4,200. The total number of small-pox burials recorded was 239 out of 1,743 burials in all. For the thirty-seven years 137 per 1,000 of the deaths of those buried (13.7 per cent.) were caused by small-pox. During the nineteen small-pox years 23.6 per cent. were caused by small-pox, and during the eight worst years the ratio of small-pox burials was 34 per cent.

The following table presents the comparative ratio of small-pox deaths to deaths from all causes in the pre-vaccination period in certain communities where records were kept:

COMPARATIVE RATIO OF SMALL-POX DEATHS TO DEATHS FROM ALL CAUSES.

	Deaths from all causes.	Deaths from small-pox.	Ratio per 1,000 deaths from all causes.
Pudsey, 1777–1813	1,743	239	137
Kilmarnock, 1728–1764	3,860	622	161
Chester, 1774	546	202	369
London, 1779–1813	668,888	55,178	82

CONTRIBUTIONS OF DIFFERENT AGES TO 1,000 SMALL-POX DEATHS AT ALL AGES.

		Under one year.	Under five years.	Under ten years.	Over ten years.	Age not stated.	Total.
Pudsey. 1777–1813.	Deaths	38	192	219	4	15	239
	Deaths per 1,000	170	861	982	17	...	...
Kilmarnock, 1728–1764.	Deaths	118	563	606	7	9	622
	Deaths per 1,000	192	918	988	11	...	...
Chester. 1774.	Deaths	51	180	202	..	...	202
	Deaths per 1,000	252	891	1,000	..	...	...

To the foregoing may also be added the figures for Geneva for the period 1580 to 1760, which showed that in that period 961 out of every 1,000 deaths from small-pox were those of children under ten years of age.

"In the town of Pudsey," says Dr. Hunter, "the epidemics prevailed every three, four, or five years, and were present in half the years of the period, which simply means that small-pox, having cleared off all the available or susceptible children, had to wait until more children came into the world for it to prey upon." In this town small-pox caused more deaths than any other disease, the whole number being 239, while consumption, the next most destructive disease, caused only 173 deaths.

Vaccination in Different Countries.—At the present day vaccination laws are enforced more rigidly in Germany than they are in any other country. In Germany revaccination is compulsory, as well as vaccination. In Sweden and Great Britain the laws are not so rigidly enforced. The following statistics relative to the mortality from small-pox in these countries and in other countries where the laws are not compulsory are instructive, and have an important bearing upon the value of vaccination. The figures are from the "Report of the Imperial Board of Health of Germany for 1890," as presented by Dr. Rahts.

MORTALITY FROM SMALL-POX IN 1890.

	In Germany.	In 229 German cities.	In 57 Austrian cities.	In 12 Hungarian cities.	In 15 largest Swiss cities.	In 69 Belgian cities and towns.	In 93 French cities of over 20,000 inhabitants.	In 28 English cities.	In 69 chief Italian cities and towns.
Census population	49,205,373	11,349,568	3,010,472	882,395	480,388	1,992,601	7,204,254	9,715,559	5,180,748
Deaths from small-pox, 1890.	58	29	473	29	13	220	1,058	10	1,306
Death-rate per 100,000	0.12	0.26	15.7	3.3	2.7	11.04	14.7	0.1	25.2

The following table gives the data for twelve principal countries of Europe for the four years 1886–1889:

Countries.	Population.	Deaths from small-pox.				Yearly average.	Average annual death-rate per million inhabitants from small-pox.
		1886.	1887.	1888.	1889.		
Germany	47,923,735	197	168	112	200	169	3.5
Belgium	5,940,365	1,213	610	865	1,212	975	164.0

Scotland	4,013,029	24	17	....	6	11.75	2.9
Ireland	4,808,728	2	14	3	....	6.0	1.0
Italy	29,717,982	....	15,249	18,110	13,416	15,925	536.0
Holland	4,450,870	72	18	1	10	25.0	5.7
Austria, about	23,000,000	8,794	9,591	14,138	...	10,841	471.0
Russia (European)	92,822,470	16,938	25,884	....	....	21,411	231.0
Sweden	4,746,465	1	5	9	2	4.25	0.9
Switzerland	2,922,430	182	14	17	3	54.0	18.5
Spain (36 provinces)	11,864,000	....	....	14,378	8,472	11,425	963.0

In the vigorous discussion which took place May 5, 1891, in the French Academy of Medicine upon the advisability of compulsory vaccination and revaccination, the question was finally put to vote, and resulted in an almost unanimously favorable vote; there were only five negative votes.—*Bulletin Acad. Méd.*, 25, 710, 1891.

The following statistics which were brought out in that discussion are worthy of note:

MORTALITY FROM SMALL-POX IN PRUSSIA PER 100,000.

(*Bulletin de l'Acad. de Méd.*, 25, 95, 1891.)

Year.	Army.	People.
1835	3.7	27.1
1840	1.6	16.0
1850	0.8	15.7
1862	0.5	21.1

One of the most valuable reports of modern times, bearing upon the subject of the value of vaccination, is the report of Dr. F. Barry, upon the epidemic of small-pox in Sheffield, in 1887–88. Dr. Barry, who is an inspector of the Local Government Board of England, was instructed to inquire into every influence which could possibly bear upon the epidemic of small-pox at Sheffield. After making a most thorough and searching investigation, as his report shows, no influence could be discovered beyond the single dominating one of vaccination.

Dr. Buchanan's introductory to this report sums up the results as follows :

	PER 1,000 OF EACH CLASS STATED.			
	Attack-rate.		Death-rate.	
	Vaccinated.	Unvaccinated.	Vaccinated.	Unvaccinated.
Up to ten years	5.0	101	0.09	44
Living in invaded houses	78.0	869	1.0	381
Over ten years	19.0	94	1.0	51
Living in invaded houses	281.0	686	14.0	371
All ages	15.5	97	0.7	48
Living in invaded houses	230.0	750	11.0	372

In the foregoing table the figures represent the rates per thousand of the child population under ten years, of persons over ten years of age, and of persons of all ages ; first, as applying to the population of the borough generally, and secondly, as applying to the enumerated population of the invaded houses. In a brief summary Dr. Buchanan further says, " the vaccinated children had, as compared with the unvaccinated in the same town, a twenty-fold immunity from attack by small-pox, and had a four-hundred-and-eighty-fold security against death by small-pox ; that in the invaded houses the vaccinated children had, as compared with the unvaccinated, an eleven-fold immunity from attack by small-pox, and a three-hundred-and-eighty-one-fold security against death by small-pox, and that as regards all ages the vaccinated among the population generally had as compared with the unvaccinated, a six-fold immunity against attack, and a sixty-four-fold security against death."

In a valuable report upon the subject of vaccination made by Dr. A. Proust, to the Consulting Committee of Public Hygiene of France, in May, 1889, he states that it is impossible to know the exact number of deaths from small-pox in France. The following, however, were known to have occurred in the fifty-three principal cities in 1886 and 1887. There were 2,991 deaths from this cause among 6,337,772 inhabitants in these cities in 1886, and 1,955 deaths among 6,361,011 inhabitants in 1887. In Paris there were, in 1870, 10,549 deaths from small-pox, and 2,777 in 1871.

A large portion of Dr. Proust's report is devoted to the demonstration of the fact that Prussia, with an almost absolute practice of vaccination and revaccination, has had a nearly complete immunity from small-pox mortality, which is very striking when compared with the deaths from small-pox in other and neighboring European countries under optional laws.

Dr. Düms, a German staff officer, communicates to the *German Quarterly Journal of Hygiene*, vol. xxi., 1889, the following statistics relative to Leipsic during the period 1872–74.

The percentage of *vaccinated* school children in Leipsic for the three years previous to the introduction of compulsory vaccination, was as follows :

1872..... 94.97 per cent.
1873..... 93.83 " "
1874..... 91.20 " "

This falling off was due to the spread of anti-vaccination sentiments.

Out of this number the percentage of those who contracted small-pox was as follows :

1872..... 0.7 per cent.
1873..... 1.0 " "
1874..... 0.9 " "

Of the *unvaccinated* children (according to their parents' statements) the percentage of those who took small-pox was as follows :

1872..... 44.1 per cent.
1873..... 44.6 " "
1874..... 63.4 " "

A paper by Surgeon-General Sir William Moore, in the *Sanitary Record* of October 15, 1891, treats of the prevalence of unchecked small-pox, and of the effect of vaccination in India. In reply to a general question sent to the sanitary officials of India as to what diseases have been lessened in India by sanitary measures, all specified small-pox. The Sanitary Commissioner of Madras stated that the city of Madras afforded an excellent example of the protection afforded by vaccination.

The following table gives the deaths from small-pox in each year in Madras, from 1871 to 1890. The population in 1881 was 405,848.

Years.	Deaths from Small-pox.	Years.	Deaths from Small-pox.	Years.	Deaths from Small-pox.
1871.....	234	1878.....	447	1885.....	56
1872.....	658	1879.....	910	1886.....	1
1873.....	1,062	1880.....	869	1887.....	13
1874.....	809	1881.....	1,654	1888.....	36
1875.....	196	1882.....	355	1889.....	45
1876.....	421	1883.....	1,957	1890.....	69
1877.....	6,758	1884.....	4,064		

Vaccination was made compulsory in Madras in 1883.

The following figures furnished by the Sanitary Commissioner of Berar, show the results of vaccination in that province :

Five-year period.	Mean ratio per 1,000 of the population successfully vaccinated.	Mean death-rate from small-pox per 1,000 of the population.
1868–1872	8.9	2.02
1873–1877	25.7	1.56
1878–1882	31.2	0.58
1883–1887	34.6	0 38

The decrease of the small-pox death-rate, conjointly with the increase in the vaccination-rate, is strikingly illustrated in the foregoing table.

The following table presents the progress of vaccination at decennial periods in the different provinces of British India:

Provinces.	Number of Successful Vaccinations at the Periods Mentioned.		
	1870–71.	1879–80.	1889–90.
Bengal	324,266	1,363,925	1,769,525
Madras	282,942	587,810	831,499
Bombay	397,622	581,051	890,820
N. W. Provinces of Onde	237,298	530,806	710,849
Punjaub	292,689	444,710	764,282
Central Provinces	102,035	288,367	350,528
Berar	17,476	74,303	92,629
Coorg	534	3,417	7,165
Assam	.....	21,170	134,922
British Rajpootana	5,996	3,695	11,510
Burmah	.....	65,293	112,428

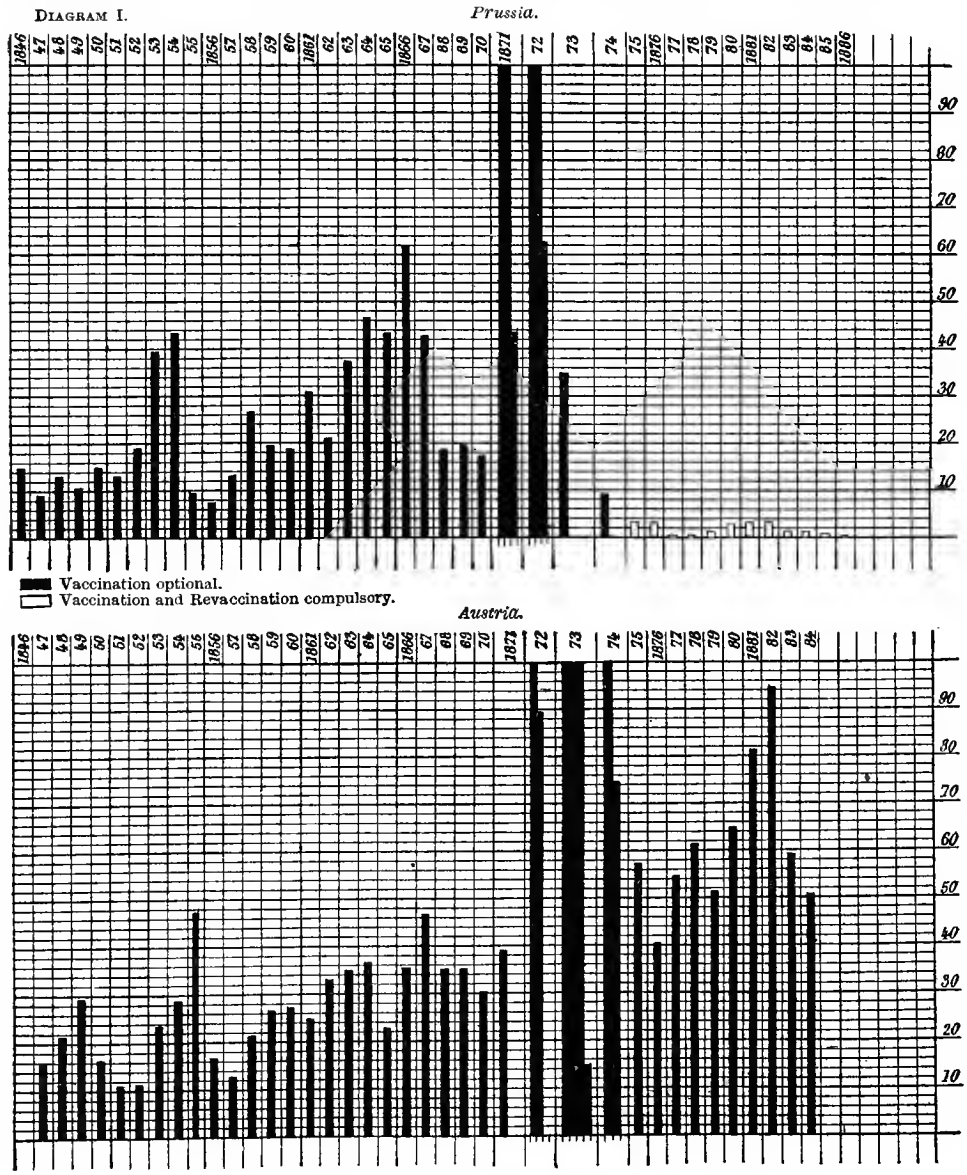
The last annual report of vaccination for the whole of India gives a total of 5,709,462 successful cases, varying in the different provinces from fifty-six to seventy-three per cent. of births.

Surgeon Moore testifies that this large yearly ratio of vaccination in India has had a very marked effect in the reduction of small-pox in that country.

He also states his experience in India before vaccination had been generally introduced. He says he marched during an epidemic of small-pox a distance of one thousand miles, surrounded by small-pox. "Those suffering from the disease in a minor degree were in the streets, generally children, occupied in their accustomed play; or if too ill, lying neglected on the ground; and these represented a portion of the whole suffering from small-pox, the remainder, unable to leave their dwellings, awaiting death in their houses. Any one cognizant of the after-effects of small-pox will at once understand the amount of suffering which must occur among those recovering from the immediate disease. The consequent effects on the eyes, the ears, the skin, the limbs,

MORTALITY FROM SMALL-POX IN PRUSSIA, AND IN AUSTRIA, PER 100,000 INHABITANTS, FROM 1846 TO 1886.

DIAGRAM I.



the joints, and the general constitution, at least equal in gravity the direct consequences of the disease. Roughly speaking, from calculations based on observing the people passing through the streets of certain cities, ten per cent. had lost the sight of one or both eyes, and an equal number had permanent injury of some organ or member; and of these affections the great majority could be traced to small-pox. From special inquiry I found nearly eighty per cent. of the population were more or less marked with small-pox."

According to the *British Medical Journal* there were in the last epidemic of small-pox in Guatemala twenty-five thousand deaths from the disease. In that country there are no vaccination laws. Its population is about one-half as large as that of New England, in which there have not been so many small-pox deaths in the last seventy-five years combined. The *Journal* characterizes Guatemala as an "autivaccination paradise." (*Brit. Med. Journ.*, 2, 1891, p. 1135.)

On the Prophylactic Power of Vaccination.—At the Tenth International Medical Congress in Berlin, in 1890, Dr. Victor Desguin, of Antwerp, said that the medical inspection of schools in that city had been organized in a very complete manner since 1882, at which time revaccination was ordered for all school children who were twelve years old. It is performed with lymph, under every possible condition of security. It is furnished by the Central Vaccinal Institute of Belgium, and before delivery of the lymph, an autopsy is made upon the animal from which it has been taken, to determine its condition of health, none being issued if the animal is found to be diseased. So that there is no danger of communicating either syphilis or tuberculosis.

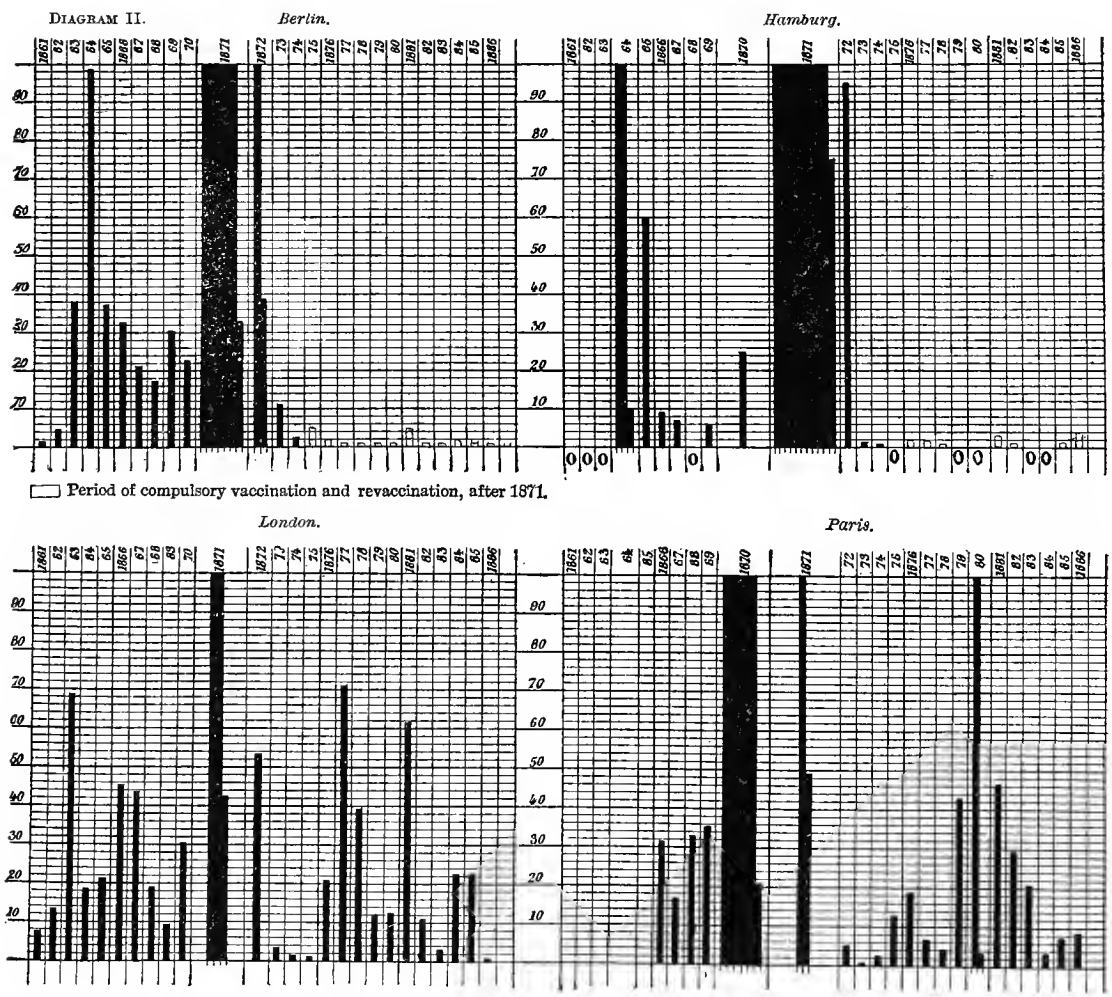
In nine years, fifteen thousand two hundred and fifty-nine children have been vaccinated, of which eight thousand and thirty-three, or fifty-two per cent., were successful. He says this ratio of success in revaccination is probably due to the fact that a considerable number of children enter the schools with false certificates of vaccination, either on account of inefficient performance, or by reason of its omission.

Revaccination was not followed in any case by unusual results, beyond what could easily be controlled, the school registers giving the particulars as to absence in all cases.

Moreover, he says that revaccination has never been followed by the development of scrofulous symptoms; a fact which he attributes to the plan adopted for strengthening feeble school-children by proper medical means.

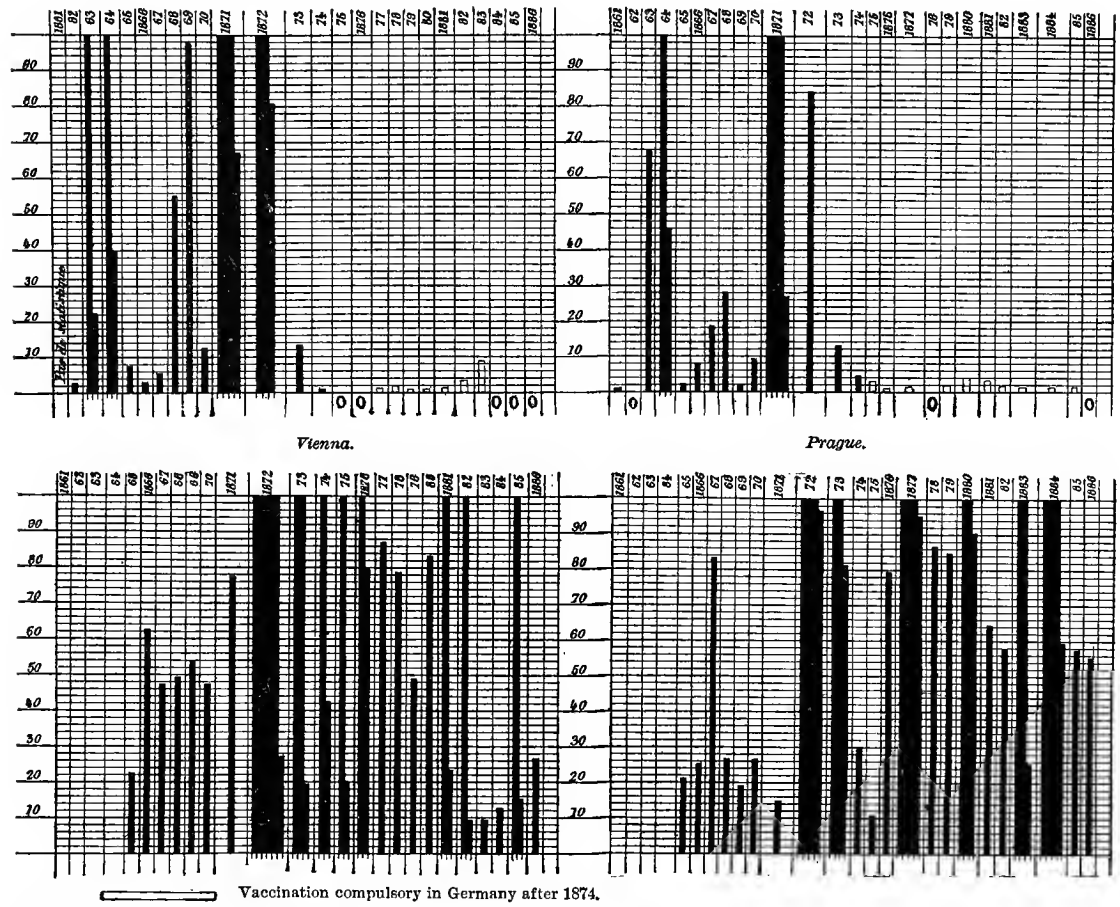
During this period of nine years there were in Antwerp four hundred and ninety-seven deaths from small-pox, only two of which were those of school-children. They were children of seven and eight years, neither of whom had been revaccinated, and one had never been vaccinated. During this period there were, among an average annual school population of thirteen thousand five hundred and six children (subject to yearly renewals and changes), fifty-three cases of small-pox, none of

Mortality from Small-pox in Several Large Cities per 100,000 Inhabitants.



MORTALITY FROM SMALL POX IN SEVERAL LARGE CITIES PER 100,000 INHABITANTS.

DIAGRAM III.



which were among revaccinated children. (Transactions of Tenth International Medical Congress at Berlin, vol. v., No. 15, p. 144.)

As an illustration of the convincing effect which a severe epidemic of small-pox has upon a population but partially protected by vaccination, the experience of Montreal may be cited, the following quotation being taken from the health officer's report for 1891. The loss by small-pox in Montreal in the epidemic of 1885, was 3,164, or about two per cent. of the whole population of the city.

"The prejudice which existed against vaccination at the time of the last epidemic is disappearing year by year. The past year, and particularly in the autumn, when the cases of small-pox scattered throughout the Province, gave reason to fear that Montreal would again be invaded by the loathsome disease, a vast number of people who hitherto had refused to submit to vaccination, not only gladly accepted the services of the vaccinators when they presented themselves, but many of them applied to the health department to have the vaccinators sent to their homes. The vaccinators had to keep their offices open every evening up to nine o'clock, even Sundays and holidays, for the convenience of those who were unable to go at a more suitable time. It is to be hoped that the small number of people yet opposed to this measure may continue to decrease, and then we shall be able to flatter ourselves that we have a city the best protected against small-pox of any on the American continent."

The advantages of a system of compulsory vaccination and revaccination in protecting large communities from small-pox are clearly shown in the diagrams presented upon pages 928, 929, 930, and 931, copied from Schulz, Impfung, Impfgeschäft und Impftechnik, Berlin, 1888, and the 19th Report of the Consulting Committee of Public Hygiene of France, 1889.

Diagram I. presents the statistics of mortality from small-pox in Prussia, and in Austria, showing the death-rate per 100,000 from this cause in each country for a period of nearly forty years, 1846 to 1886, in Prussia, and 1847 to 1884, in Austria. Vaccination was optional for the civil population in Austria for the whole period, while in Prussia it was compulsory after April 1, 1875.

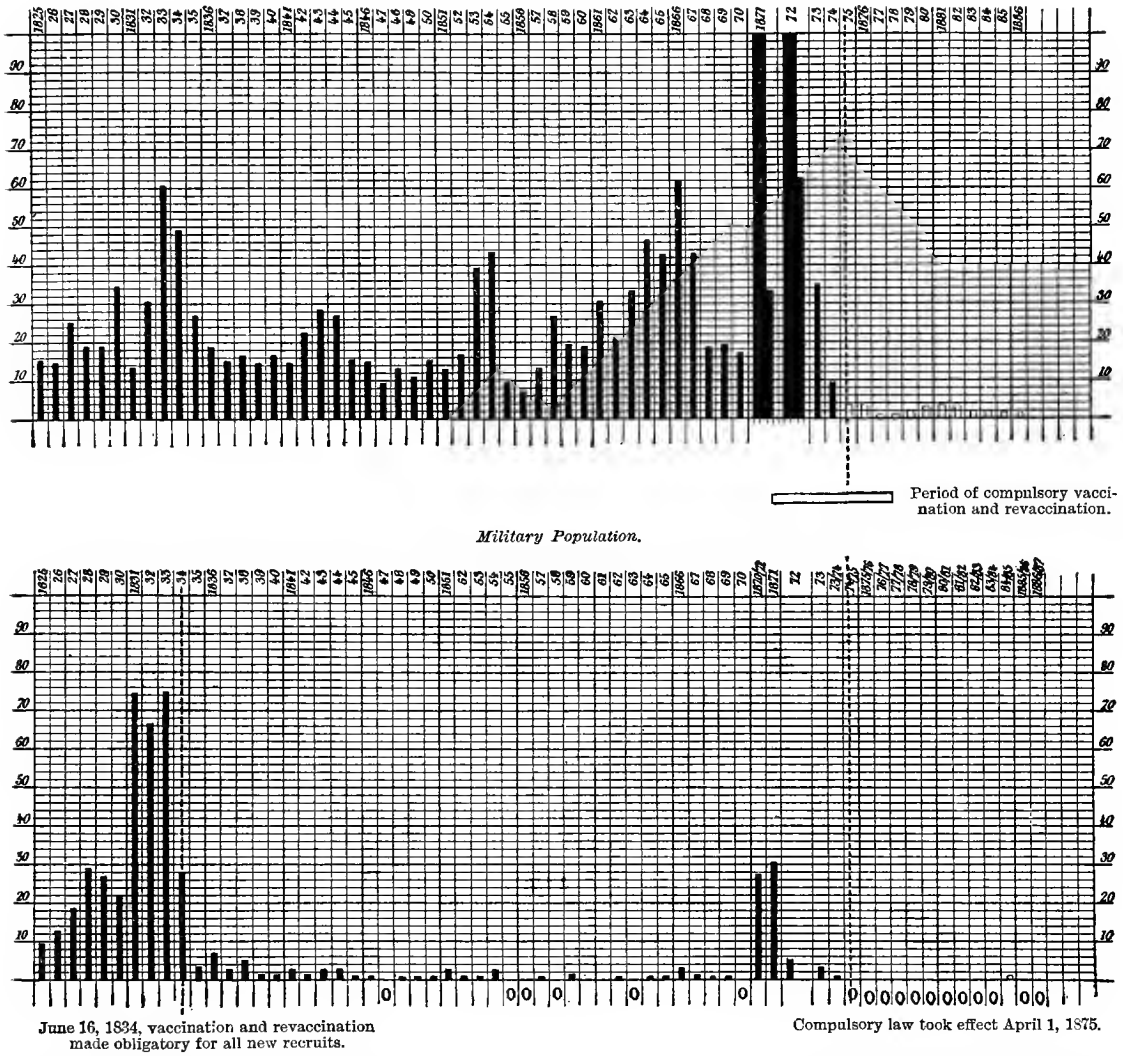
Diagrams II. and III. present the comparative mortality from small-pox, of four German cities in which vaccination was compulsory after 1875, and that of four other large European cities in which it was either optional, or optional in the case of revaccination for the whole period (1861–1886) as it was in London.

Another diagram, No. IV., presents the condition of the civil and military population of Prussia, with reference to the same subject, for the period of sixty-two years, 1825–1886. Vaccination and revaccination of all new recruits was required by law after June 16, 1834, but not for the civil population till 1875. When the law requiring all persons to be vaccinated in infancy, and revaccinated at twelve years, became operative, it appears to have reduced the small-pox mortality to very small limits among the civil population, and to a still greater extent among the military population (one death only from this cause in thirteen years).

The renowned statistician Körösi, of Buda-Pesth, has

MORTALITY FROM SMALL-POX PER 100,000 INHABITANTS IN THE CIVIL, AND THE MILITARY, POPULATION OF PRUSSIA, FROM 1825 TO 1886.

DIAGRAM IV.



continued his convincing series of statistics (mentioned in Vol. VII. of the REFERENCE HANDBOOK, p. 528), adding to the published data of 1886 those also of 1887 and 1888, which were derived from the hospitals and cities of Hungary. He contends that the ordinary comparisons of small-pox mortality in the periods before and after the introduction of vaccination, and the mortality from small-pox in countries and cities well or poorly vaccinated, do not constitute convincing proof of the value of vaccination. He entertained the idea that the proof could only be sustained when, in populous districts, the total number of the vaccinated and the unvaccinated is known, from which it would be easy to learn the mortality from small-pox among the vaccinated and the unvaccinated. But to obtain these figures from whole countries is not an easy task. The author's new method permits of a proof in figures of the influence of vaccination without a necessary knowledge of the number of the living vaccinated and unvaccinated. Until his inquiry was made, the vaccination question had been made to depend on the number sick or deceased from small-pox.

The tables which Körösi has published contain the number of persons treated for the most diverse diseases, and dying of the most diverse causes, their ages, and also whether vaccinated or unvaccinated. One table contains the condition as to vaccination of 53,320 persons treated in 1886, 1887, and 1888, in nineteen Hungarian hospitals. The second table presents the statistics of 5,518 deaths in the same hospitals, and for the same period. A third table gives the statistics of 58,639 deaths in ten Hungarian cities for the same years, from different causes.

Of the persons sick with different diseases in the hospitals, 11.75 per cent. were unvaccinated. If vaccination had no effect upon small-pox *morbidity*, then the unvaccinated would have shared to the rate of about 11.75 per cent. in the contemporaneous 1,912 cases of small-pox. In other words, there would have been two hundred and twenty-five cases of small-pox among the unvaccinated. Instead of this the number of cases of small-pox among the unvaccinated was seven hundred and twenty-six. The neglect of vaccination, therefore, increased the liability to small-pox 3¼ fold. In the same manner the author concludes that the danger of death from small-pox is six times as great among the unvaccinated.

He also estimates that skin diseases destroy two per-

sons out of every million, while by vaccination two thousand are saved.

COMPULSORY VACCINATION.—Dr. Brouardel, in a spirited address before the French Academy of Medicine, March 3, 1891, advocated compulsory vaccination in the most eloquent language. He laid much stress upon the results of Dr. Barry's inquiry as to the prevalence of small-pox at Sheffield. He attacked the position of M. Fort, who claimed that the diminution of small-pox at the present day is due to isolation and disinfection, and not to vaccination.

He said that the display of quarantine flags or signals could not avail in all cases to prevent access to those who were ill with infectious diseases. When the Queen of Holland was attacked with measles, "the flag did not keep people away from the palace. Anyone went to see her."

Furthermore, he said, "I attach great importance to the German law of 1874. All children attend school, all children must be revaccinated. That is just what we need in France."

With reference to the prevalence of small-pox at Leicester, England, in common with other English towns, in November, 1892, *The Lancet* says (November 19th): "Dr. Coupland has visited Leicester on behalf of the Royal Commission on Vaccination. The results of his inquiry are unknown; but they may be taken to include an account of the failure of the much-vaunted quarantine system on almost the first occasion when that scheme has been put to any semblance of a real test."

PRESENT PRACTICE OF VACCINATION IN DIFFERENT COUNTRIES. GERMANY.—Undoubtedly Germany has at the present day the most thoroughly vaccinated population in the world, since the compulsory law of that country is the most efficiently enforced.

The following figures present the numbers of the vaccinated and revaccinated, for the years 1888–89:

Total number liable to vaccination, 1888	2,678,056
Total number liable to primary vaccination, 1889, after excluding exempts	1,458,393
Total number liable to revaccination, 1889	1,224,507
Total	2,682,900
Total number vaccinated in 1888	2,487,484
Total number vaccinated (primary), 1889	1,299,981
Total number revaccinated, 1889	1,185,504
Total	2,485,485
There remained unvaccinated (primary), 1889	158,412
There remained unvaccinated subject to revaccination, 1889	39,003
Total	197,415
Of the foregoing there were vaccinated with humanized lymph, in 1888, a total of	545,231
Those vaccinated with humanized lymph in 1889 were	135,259
Those revaccinated with humanized lymph in 1889 were	123,942
Total	259,201
The total number vaccinated with calf lymph in 1888 was	1,942,356
The total number vaccinated with calf lymph (primary) in 1889 was	1,168,003
The total number revaccinated with calf lymph in 1889 was	1,057,193
Total	2,225,196

England and Scotland.—In England, in 1889, the statistics were as follows:

Number of births	885,909
Successfully vaccinated	707,161
Reported as insusceptible	1,758
Had small-pox	2
Died unvaccinated	88,995
Vaccinations postponed	13,366
Remaining	74,627

The percentage of children not accounted for, as compared with the births, was 9.9; that of 1888 having been 8.5.

VACCINATIONS IN SCOTLAND, 1885*–1890, AND PERCENTAGES TO BIRTHS.

	Successfully vaccinated.	Vaccination postponed.	Insusceptible. From constitutional insusceptibility.	Insusceptible. From having had small-pox.	Insusceptible. From previous vaccination.	Died before vaccination.	Removed from district before vaccination, or otherwise unaccounted for.	Total births.
1885...	109,866	2,073	225	0	228	10,872	2,888	126,152
1886...	110,864	2,325	201	0	241	11,282	3,055	127,968
1887...	107,077	2,465	236	0	373	11,269	3,047	124,467
1888...	106,734	2,417	216	0	397	10,434	3,096	123,294
1889...	104,931	2,692	235	0	256	11,479	3,226	122,849
1890...	103,635	2,710	222	2	248	11,779	3,016	121,612
PERCENTAGES OF BIRTHS.								
1885...	87.1	1.6	0.2	0	0.2	8.6	2.3	100.
1886...	86.6	1.8	0.2	0	0.2	8.8	2.4	100.
1887...	86.1	2.0	0.2	0	0.3	9.1	2.4	100.
1888...	86.6	2.0	0.2	0	0.3	8.5	2.5	100.
1889...	85.4	2.2	0.2	0	0.2	9.3	2.6	100.
1890...	85.2	2.2	0.2	0.002	0.2	9.7	2.5	100.

* See p. 521 of Vol. VII. for statistics of earlier years—1880–1884.

If the number of births who died in each year before they could be vaccinated is deducted from the total number of births, the number successfully vaccinated is found to be about ninety-four, or ninety-five per cent. of the surviving births for Scotland for the period 1885 to 1890.

Japan.—The following table, presenting the number of vaccinations in Japan in 1888 and 1889, may be compared with the statistics of the same country for the period 1875 to 1879. (See REFERENCE HANDBOOK, Vol. VII., p. 522.)

TOTAL VACCINATIONS IN 1888 AND 1889.

	Successful. 1888.	Successful. 1889.	Unsuccessful. 1888.	Unsuccessful. 1889.

Austria.—(*Recueil des travaux du Comité Consultatif d'hygiène publique de France.* 19, 1889.) There were in 1885, 15 vaccinal institutes in Austria: 3 in Vienna, 3 in Prague, 5 in Styria, 2 in Galicia, 1 in the Tyrol, and 1 in Linz.

The number of persons vaccinated in Austria in 1885 was 951,364, or 4.3 per cent. of the population. The number of unsuccessful vaccinations, so far as it was known, was 19.8 per cent., as compared with 18.9 per cent. in the previous year, and 19.2 per cent. in 1883.

Seventy-one and three-tenths per cent. of the vaccinations were made with liquid, and 28.7 per cent. with solid vaccine, the latter mostly in Gallcia and Bukowina.

The expenses of vaccination amounted to 183,127 florins (about $85,000). The cost of each vaccination varied from about six cents in Bukowina and Lower Austria to twenty-eight cents in Trieste.

France.—Dr. Proust's report to the French Consulting Committee of Public Hygiene presents many valuable tables relating to vaccination, of which a condensed summary is herewith given.

The number of vaccinations gratuitously furnished by the Academy of Medicine, from 1871 to 1887 inclusive, including primary vaccinations and revaccinations, was 82,553. During the same period the Academy distributed gratuitously portions of vaccine lymph as follows:

Plaques	182,651
Tubes	27,315
Points	96,718

The Academy of Medicine also furnishes the following statistics for France:

1875 to 1885.

Years.	Births.	Vaccinations.	Revaccinations.	Cases of small-pox.	Deaths from small-pox.	Percentage of vaccinations to births.
1875.....	803,243	554,773	13,710	4,103	698	69.1
1876.....	716,988	558,855	6,453	7,211	1,068	77.9
1877.....	773,208	578,969	14,883	9,510	1,662	74.9
1878.....	799,270	604,182	8,734	14,181	3,300	75.6
1879.....	771,424	588,348	8,115	8,478	1,302	76.3
1880.....	739,436	658,987	49,842	17,579	2,997	89.1
1881.....	752,287	631,122	29,079	14,103	3,430	83.9
1882.....	734,628	601,508	34,949	34,746	2,297	81.9
1883.....	517,456	460,813	45,518	6,125	1,517	89.1
1884.....	720,454	587,761	28,317	8,910	2,104	81.6
1885.....	737,246	611,190	30,990	8,948	1,727	82.9
	8,065,640	6,436,508	270,590	133,894	22,102	79.8

Dr. Proust also presents a table of the vaccinations and revaccinations performed in the city of Paris from 1877 to 1886, and in the hospitals and bureaus of charity from 1886 to 1888. The least number was 27,689 in 1877, and the greatest 69,309 in 1888.

Cases of Vaccinia in the Cow.—In the seventh volume of this work mention was made of various attacks of cow-pox among the herds in different dairy-farms, both in Europe and in America. Scarcely a year passes without the report of one or more cases. The disease rarely becomes epidemic over a territory of considerable size, but is usually confined to the milk-giving animals in one dairy. It was once common to apply the term "spontaneous" to these cases. Present knowledge of the natural history of infectious diseases, however, teaches us to discard the use of this term, which appears to have been employed as a confession of ignorance as to the cause of the disease. Even if we know no more as to the true cause of diseases than was known half a century since, this may be said: The absence of knowledge as to a pre-existing cause does not by any means justify us in asserting that such cause does not exist.

A very careful report of an epidemic of vaccinia is presented in the Eighteenth Report of the Local Government Board of England (Supplement containing the report of the Medical Officer for 1888). It was reported to that Board in June, 1888, that an eruptive disease was prevailing among the cows at a certain dairy in Alderley, a small town in Gloucestershire. The farmer's son and several other persons had contracted an eruption while milking this herd. Dr. Klein visited the place, and on inspecting the herd and the milkers, concluded that it was vaccinia. Most of the persons had nearly recovered from the eruption. But one girl, aged twenty, had a recent eruption on the right thumb consisting of one vesicle. Dr. Klein obtained a capillary tube of lymph from this vesicle, together with some crusts from the cows which had been attacked. The vaccinations with the crusts failed completely, but some which were removed at an earlier stage from other animals gave striking and positive results of true vaccinia. The lymph from the vesicle upon the thumb of the milk-maid also produced positive results. From these other calves were inoculated, and tests were made of the lymph obtained. The final results were those of typical vaccinia. Dr. Klein's observations were confirmed by those of Drs. Cory and Messrs. Murphy and Collins. In Dr. Buchanan's comment upon this case he says, the disease "had the characters of that 'variolæ vaccinæ' which Jenner discovered in the same county in the last century, and which he put to the purpose of protecting against small-pox."

Not far from the foregoing case, at Cricklade, in the neighboring county of Wiltshire, other cases of cow-pox were discovered in the autumn of 1887, of which an account is given in the second volume of Crookshank's "Vaccination: Its History and Pathology." This region also is not far from the district in which Jenner made his early observations. In a herd of one hundred and twenty cows here, all were attacked except a dozen, which proved refractory. Vesicles appeared on the teats, two, three, four, or more on each teat. These were soon broken in milking, and irritated into sores, which became covered with thick crusts. From four to six weeks elapsed before they healed. The cows generally appeared to be in good health. The milk-supply was slightly diminished, so that by a rough estimate the owner estimated his loss of milk in the whole herd at £50. A striking characteristic of this outbreak was the communicability of the disease to the milkers, of which Dr. Crookshank details eight well-marked cases.

Successful vaccinations of calves were made from this outbreak.

The Question of Unity or Duality of Variola and Vaccinia.—In 1865 a commission at Lyons published the following conclusions relative to the relation of these diseases to each other:

1. Cow-pox and small-pox can be inoculated in bovine and equine animals; the first energetically, the second feebly.

2. Whatever may be their successive transmissions, direct or crossed, these two diseases breed true on every soil.

3. The protection from one by the other is assured in every case.

Some interesting experiments have been recently made by Haccius and Eternod, of Geneva, which tend to confirm those already published by Fischer in the *München med. Wochenschrift*, and make the identity of variola and vaccinia more than probable. The conclusions at which Thiele, Ceely, Voigt, and Depaul arrived many years ago, namely, that cow-pox is a modified form of small-pox, attenuated by its passage through the organism of an animal, were disputed by the Lyons commission, which adduced seemingly unimpeachable experiments of their own, contradictory to the observations of the earlier experimenters.

Haccius and his colleague, following the operative method of Fischer, claim that they have succeeded in imparting small-pox to animals, and in transmitting it through several generations, the disease finally manifesting itself in a mild form not distinguishable from true cow-pox, and like it, conferring immunity from variola.

Believing that the method of inoculation by pricks and incisions practised by the Lyonese commission was insufficient, and that experiments based upon this method

were inconclusive, these later experimenters resorted to a procedure which they call *vaccination in surface*, or *vaccination by denudation*. Fischer's method was by extensive scarification. Haccius and Eternod denude the skin of the animal over an extent of several square centimetres by means of a thin glass scraper. A little hemorrhage follows, and then some oozing of serum, which they carefully wipe off by means of a sterilized cloth. Then they rub the denuded surface with a spatula charged with the small-pox virus. They assert that by this procedure they have never failed to obtain success, while the method by pricks and incisions is apt to fail.

They found that in the first generation there is produced a local eruption accompanied by "spontaneous" pustules, always small in number, the entire eruption having an aspect but little typical, somewhat abortive, and this, they think, was what led the Lyons commission into error. If from the product of these papules another series of inoculations is practised, and then another from the results of the second, the appearance soon changes; at the end of the second or third generation the pustulation tends to become typical, by taking on more and more the mode of evolution and the characters of the vaccinal eruption. After the third generation, "an expert would assuredly have difficulty in distinguishing the pustules in these animals from those that are obtained in the vaccinal institutes by the inoculation, in the first generation, of spontaneous cow-pox."

In each animal the counter-proof was carefully made with animal vaccine. All the animals that had been before inoculated with small-pox virus were invariably refractory to vaccine.

In one of these series of experiments, Haccius and his colleague succeeded in transmitting the small-pox virus from heifer to heifer to the fourteenth generation; and side by side with a set of similar observations where vaccine virus was used, they had a series under observation where the heifers were inoculated with virus from a case of confluent small-pox. Lymph from "the fourth generation" has given the results of ordinary vaccine when used for purposes of vaccination.

Their conclusions were as follows:

1. Variola is inoculable *with certainty* on the bovine species when the operative method is such as it should be, and the virus is collected at the opportune moment.

2. The inoculation of small-pox to the heifer constitutes a precious source for new reinforcements of animal vaccine. This may be of great practical benefit, not only to the vaccinal institutes of Europe, but also to tropical countries, where small-pox is endemic, and where the generations of vaccine tend rapidly to deteriorate.

3. Small-pox inoculated in the heifer becomes transformed into vaccine in the course of several generations, by transmission through the animal. *Duality is thus disproved.*

4. Our practical conclusions confirm the views enunciated by Depaul, in 1863, to the Academy of Medicine of Paris.

Following these experiments Chauveau obtained lymph from the Genevan professors and submitted it to experiment. It was the product of the eighth transmission from heifer to heifer. Chauveau's trials were made exclusively on subjects of the bovine species. The primary eruption which follows the inoculation constantly maintains special characters which, in his opinion, differentiate it from the vaccinal eruption. At the same time, this special eruption is the result of an infection which has close relations with vaccine, for it is no longer possible to *vaccinate* animals thus *variolized*. M. Chauveau finds no evidence of that transformation of small-pox into the vaccine disease which the Genevan professors claim to have effected by passing their lymph through a succession of cattle, the original virus being variolic. The experiment was a repetition of experiments which, as one of the members of the famous Lyons commission, he had performed many years before.

M. Chauveau's paper (*Sur la transformation des virus à propos des relations qui existent entre la vaccine et la variole*) was presented at the sessions of the Academy of Medicine of October 20 and 27, 1891. His conclusions are as follows: (1) Vaccine virus never gives small-pox to man. (2) Variolic virus never gives vaccine to the cow or horse. (3) Vaccine is not even *attenuated small-pox*, and cannot be compared to the benign anthracoid infection which is communicated to animals by inoculation with *attenuated anthracoid virus*. (4) If vaccine is a derivative of small-pox it is by reason of a *radical transformation* of the variolic virus, a transformation thus far unattainable by experimenters. (5) These last propositions lead to another more general proposition, which is this: the *attenuation* of virus is not a physical process which can be identified with the *transformation* of virus.

This being granted, how, it may be asked, does vaccine virus confer immunity from small-pox?

If we do not know exactly the mechanism of this immunity, the essential cause on which it depends is well known. On reviewing all the systems of preventive inoculation, we come upon three methods which may be treated under the following heads:

(*a*) Fabrication of prophylactic substances by pathogenic agents outside of the organism to be rendered immune, and the introduction into this organism of the said substances in sufficient quantity to confer immunity, these substances having been, by the proper manipulations, freed from the virulent elements properly so called, and rendered inoffensive.

(*b*) Fabrication in the organism to be protected of prophylactic substances by the pathogenic agents with the germs of which inoculation has been made, under conditions which insure the benignity of their infectious effects.

(*c*) Fabrication of the vaccinal substance by a virus very like the virus against which immunity is sought, but belonging to another species.

In this latter category, Chauveau places the microbe of chicken-cholera in its function of conferring immunity against charbon. Here, also, he would put the virus employed as a preservative from small-pox. Whatever, in fact, may be the origin of vaccine, though we were to admit it to be a derivative of small-pox, in his opinion it none the less constitutes in reality a morbid species distinct from the latter. The two viruses, vaccinal and variolic, are, according to Chauveau, irreducible into one and the same infectious entity.

Satisfactory experiments of this kind are difficult of performance, for no experimentation on animals can be regarded as complete whose results have not been checked by inoculations practised on the human subject. Now, Haccins and Eternod did not try their lymph—rendered vaccinal, as they believed, by several removes—on the unvaccinated child, nor did Chauveau make any such trials. (*Boston Med. and Surgical Journal*, 1891.)

On the other hand, it appears that the experiment has been tried upon unvaccinated children in Calcutta, as detailed by the experimenter, Dr. W. J. Simpson, medical officer of health of Calcutta, at a meeting of the Calcutta Medical Society, April 13, 1892.

Dr. Simpson comments upon Chauveau's experiments as follows: "Seventeen animals were inoculated by that commission with lymph from virulent cases of small-pox, and some small papules were obtained, the secretions from which, when inoculated into other cows, gave rise to papules of an insignificant kind, but which when inoculated into children gave rise to small-pox. On this slender foundation the theory has been based, and is very forcibly put forward, that small-pox in man produces a real small-pox in the cow totally differing in every respect from cow-pox.

To those who have studied the subject these experiments are by no manner of means conclusive. They only show that Chauveau with his coadjutors failed to inoculate the cows successfully, and that the papules raised were rather due to the irritation of the points of insertion by the small-pox lymph, and that the serous matter taken out of these papules was the small-pox lymph itself, which had remained in them unchanged; and under these conditions it was not surprising that

small-pox was produced in the children inoculated with this virus.

Nothing further was attempted in the way of experiment until Dr. Klein, in 1879, inoculated thirty-three cows with small-pox lymph, but failed to raise any vesicles on the cows. Papules appeared in some of the cows at the seat of inoculation, but these were not considered to have turned the experiments into a success, and no serum was taken from these papules and inoculated into children. If such a procedure had met with favor, there would probably, as in Chauveau's cases, have been an after-history of small-pox in the children inoculated.

Dr. Klein's failure served to accentuate the theory based on Chauveau's disaster, and both failure and disaster were employed as a basis on which arguments were founded against the pathological identity of small-pox and cow-pox. So confident have the supporters of this view since become, that strong doubts have been expressed by them as to the genuineness of the experiments performed by previous observers. A favorite argument appears to be that what was accomplished in the earlier part of the century cannot be done now, and therefore the experiments are not altogether to be trusted. The reason of this is not far to seek. All the conditions under which the cow may be successfully inoculated are not known, and hence it is not every cow that can be inoculated with success. This entails on the investigator much expense, the exercise of a great deal of trouble and patience, and of course it is much easier to read up the subject as Professor Crookshank has done, and side with the view for which you may have the greater predilection, than thoroughly to investigate the subject, not being satisfied with dubious results.

Apart from the controversial question, it has for a long time been a matter of thought with me as to whether there is any relationship between cow-pox, horse-pox, sheep-pox, and small-pox; whether these four diseases have for their cause a common origin which may be designated by the letter x, this common origin having not yet been discovered; or whether horse-pox, cow-pox, and sheep-pox, or any of them, are descendants of small-pox; or thirdly, whether small-pox may be looked upon in the light of a parasitic disease which comes to its full development in man, enters some animal as the cow, losing that which gives it its infectious properties, and then in some other animal unknown as yet, or in the soil, regains that element which it had lost in the cow, and which once more renders it infectious.

I am inclined to think that it is in this latter direction that investigation will ultimately succeed in discovering the cause of the periodicity of small-pox.

Vaccine and chicken-pox have always seemed to be two elements of small-pox which have become separated in some unknown way, the vaccine retaining the peculiar qualities belonging to the small-pox which affects the body in such a manner as to render it immune from a second attack, while the chicken-pox has none of these qualities but has retained the infectious element. If this were true, it might seem to be easily proved by experiment. I have tried the experiment by mixing the two viruses, but without success. There is a difference, however, between mixing and combining, and it is possible that the conditions which affect this have to be found in some other less simple way.

It is for the reasons stated, and for some others which I need not mention here, that I have been engaged for years, as opportunity arose, in experimenting with small-pox on animals.

When in Aberdeen I used to search the farms in the country for cow-pox, and not without success. I have inoculated cows, horses, sheep, pigs, goats, fowls, monkeys, and dogs with small-pox virus to ascertain the result, and in these experiments I have succeeded incidentally; for it was not the primary object for which I began the investigation, in converting small-pox into ordinary vaccine by passing the virus from an unprotected small-pox patient through the cow.

In December, 1884, I first succeeded in raising a vesicle in a cow after inoculation with small-pox virus. The lymph was transferred to a ewe lamb, and raised a vesicle in every appearance similar to a vaccine vesicle. This lymph was taken and introduced into a young pig six weeks old, and here it was lost.

In November, 1885, with small-pox lymph from an unvaccinated patient, I inoculated a cow with fifth-day lymph, and a ewe with eight-day lymph from the same patient. Both presented vesicles on the seventh day, the lymph of which I sent to London to be used by Dr. Cory, the director of the Animal Vaccine Institute in London. This calf-lymph, which Dr. Cory passed through a second calf before using on children, was the starting of a new stock of vaccine at the Institute.

Between November 21, 1885, and May 6, 1886, 1,247 children had been vaccinated with this lymph, and gave 98.4 per cent. insertions of success. Meantime another observer has come forward with experimental evidence as to the close relationship between small-pox and vaccine.

Dr. W. G. King, of Madras, inoculated a calf with small-pox lymph of five days' duration, and in this a crop of secondary vesicles appeared on the eighth day. From this lymph another calf was inoculated, and there was also in this second calf a crop of secondary vesicles, with the addition that every insertion had also taken. A third and fourth generation was passed through other calves, with the insertions always taking, and no appearance of secondary vesicles forthcoming; after which the lymph in the fifth generation was used on children with the most satisfactory results. From this stock 4,240 British and native soldiers have been vaccinated, and a very large number of the native civil population, with most gratifying results, the percentages of success being much above that which was obtained from the lymph in use.

On March 4th, in the presence of three physicians of Calcutta, I inoculated a young calf with lymph from a small-pox patient on the fifth day of the eruption. On the three following days other calves were inoculated with lymph from the same patient, with lymph respectively aged six days, seven days, and eight days.

As these three last were unsuccessful, nothing further need be said concerning them. The history of the first case and the appearances noted day by day, I need not give here in detail. Suffice it to say that on the 9th of March, that is, on the sixth day of inoculation, three papules appeared in the groin and abdomen at places where there had been no punctures or incisions, and that these three papules developed the next day, on the 10th of March, into vesicles. Two of the incisions and one puncture also contained lymph. Lymph from these was taken and inserted into another calf, designated calf No. 5. Whether the papules which developed into vesicles were secondary, or caused by the rubbing of the loose skin of the abdomen, it is difficult to say. The secondary vesicles appeared on a part where the folds of the skin were likely to come in contact. Three days later, on the 13th, the vesicles, notwithstanding the fact that lymph had been taken from them on the 10th, had developed still more. On the thigh also had appeared another well-marked vesicle. With lymph from each of the vesicles a second calf, calf No. 7, was inoculated. On the 14th of March two other apparently secondary vesicles made their appearance. From the lymph extracted from one of these a child was inoculated, but it failed to take.

Both calves Nos. 5 and 7 took successfully. From calf No. 5, on March 15th, that is, the sixth day of inoculation, lymph was taken from some of the vesicles and inserted into a male child named Bonwari, and also into calf No. 10, and on the evening of the 16th lymph was taken from the other vesicles and inserted into the arm of child No. 2, Rukhua by name, and also into two calves, calf No. 11 and calf No. 12.

Calf No. 10 showed signs of being ill a day or two after, and only gave very indifferent results. The child Bonwari had, however, at the points of insertion two splendid vesicles, which ran the ordinary course of vaccine vesicles. Calf No. 11 was not successful. But calf No. 12 showed very fine vesicles indistinguishable from

those in ordinary calf vaccination. This was transferred from calf to calf through several generations.

The child Rukhua had excellent vesicles. There appeared on its body a slight lichenous eruption, but nothing more.

From Bonwari there has, up to now, been a direct descent of nine generations in children, each showing splendid vaccine vesicles, much more typical in every respect than that obtained from the lymph which had been previously in use.

From Rukhua there have been made direct nearly the same number of generations in children, and with equally satisfactory results. I stated that No. 7 calf, inoculated three days later than calf No. 5 from calf No. 1, was also successful. From calf No. 7 lymph was taken and inserted into the arm of Bassunto, child No. 5, on March 19th, and at the same time three calves were inoculated.

The three calves took, but since they were not in very good health, I thought it best not to use the lymph. (We had, unfortunately, got rinderpest among the calves.)

The child's arm, however, took splendidly, and from it other children were vaccinated with good results.

A curious incident occurred in the course of these investigations. My wife, who drew for me the vesicles on the calves, got two well-marked vesicles on her upper lip. In pointing out the parts to her on calf No. 7, I used her pencil, passing it over the vesicles. In using the pencil she put it to her lips. In a few days after there appeared on the lips two vaccine vesicles, one of which, in spite of applications of corrosive sublimate and carbolic oil, went through its natural course.

This very clear statement by Dr. Simpson was corroborated by the testimony of four other English physicians and several native physicians of Calcutta, who witnessed the experiments and testified that the result of passing small-pox virus through these calves was to produce typical vaccine vesicles.

In reply to inquiry as to precautions taken, Dr. Simpsou stated that at every stage of the procedure new lancets were used, and that the first calf was taken directly into a small-pox ward and inoculated from the pustules of a small-pox patient." (*Practitioner*, vol. xlix., July, 1892, p. 73.)

Still more recently, Dr. Thomas W. Hime, of Bradford, England, communicated an article to the *British Medical Journal*, in July, 1892, in which he details certain experiments of a similar character. He inoculated a calf with variolous lymph, and succeeded in obtaining a product which, when inoculated upon three other calves and one man, produced the characteristic symptoms of vaccinia. Seven persons were vaccinated from one of these calves with the same results, good vaccine vesicles being thus produced.

ANIMAL VACCINATION.—Public vaccinal institutes for the propagation of bovine lymph exist in Italy, Russia, Belgium, Germany, England, Switzerland, India, and Japan.

The places in Italy where such institutes exist, and the dates of their establishment, are as follows: Naples, 1849; Bologna, 1868; Milan, Bergamo, 1869; Ancona, Foggia, Genoa, Venice, Arezzo, and Verona, 1870; Vicenza, 1871; and Rome, 1872.

Those of France are located at Lyons, Saint-Etienne, Montpellier, Toulouse, Bordeaux, and Lille. There are also several private establishments in Paris.

In Germany the use of animal lymph for vaccination is yearly becoming more general, and is encouraged in the orders of the Imperial Board of Health, which makes an annual report upon the subject. The last report of that Board gives the statistics of twenty-five German cities in which are establishments for the production of animal lymph under careful supervision. Each establishment has a director, assistant, veterinary surgeon, and one or more attendants.

Only strong and healthy calves were employed for the purpose, the average cost of each being 9 to 12 marks ($2.10 to $2.75).

The principal expenses of these establishments were as follows: Salaries—director, from $115 in Weimar to $1,200 in Berlin; veterinary surgeon, $26 in Weimar to $350 in Darmstadt; clerk, $23 in Weimar to $108 in Munich; rent of establishment, $35 in Weimar to $370 in Stuttgart; procuring animals and transportation, $42 in Schwerin to $425 in Munich; care of animals, $25 in Weimar to $825 in Oppeln; heating, light, and water-supply, $2.50 in Cannstadt to $80 in Munich; cleaning, washing, and disinfection, 70 cts. in Bautzen to $35 in Berlin; packing lymph and postage, $10 in Cannstadt to $250 in Berlin; expenses of instruments, apparatus, etc., $2.50 in Bautzen to $190 in Stettin; miscellaneous, $3.00 in Schwerin to $350 in Munich.

Feeding.—The calves used for vaccination were usually fed with warm cow's milk. In the case of animals which were not very strong, two or three eggs daily for each animal were added. In the majority of instances the calves increased in weight while at the establishments, the average increase being about 2.5 kilos. (5½ pounds).

The number of animals employed in all the twenty-five cities during the year 1891 was 1,272. The greatest number employed in any one city was 149 in Cologne, and the least number, 5, in Lubeck. Their ages varied from two or three weeks to two years. The greater number were about three months old. In Stuttgart and Carlsruhe, heifers of one or two years were employed. Most of the animals were of Dutch breed, and weighed about 80 kilos. (170 pounds).

The average temperature of animals at entrance was 39.3° C. (102.8° F.), and the average temperature at the time of taking lymph was 40.4° C. (104.7° F.).

For the vaccination of animals, calf lymph was used in the greater number of instances. In some cities both humanized and animal lymph were employed. No humanized lymph was used for the purpose in Berlin, Oppeln, Leipzig, Stuttgart, Cannstadt, Carlsruhe, Lubeck, Bremen, Hamburg, and Metz.

In Munich, 76 animals were vaccinated with glycerinized human lymph.

For the purpose of vaccination, scalpels were usually employed, and these in some instances were preferably dull, the skin being scarified or slight incisions were made. In some instances instruments specially designed for animal vaccination were employed. In some of the cities disinfectants were used for cleansing the hands, instruments, and occasionally the skin of the animal. In Munich, the instruments were carefully sterilized with steam or dry heat. The place selected for vaccination was the belly from the navel backward. The milk-mirror was found to be less fitted for vaccination in consequence of its loose structure and tendency to scab or crust.

It was generally found that diarrhœa among calves stopped the development of lymph vesicles.

Product of Vaccine Establishments.—The amount of lymph obtained during 1891, in those establishments where the product was carefully weighed, was about 12,000 grammes, being an average of about 10 grammes per animal. The whole amount was sufficient for the vaccination of nearly four million children.

Collection and Preservation of Lymph.—Considerable difference prevailed in the different cities, as to the time in which lymph was considered to be sufficiently mature for collection. The following are noted with reference to the principal cities:

In Königsberg, 73 to 119 hours after insertion of lymph.

In Berlin, usually 72 hours. In a few cases 6 hours earlier, or 3½ hours later.

In Hanover, 96 hours, in a few cases 82 hours.

In Munich, at end of the fourth or beginning of the fifth day.

In Dresden, 3 to 4½ days.

In Bautzen, 86 hours.

In Cannstadt, 87 to 97 hours.

In Carlsruhe, as a rule 84 hours.

In Darmstadt, 72 to 135 hours.

In Weimar, 84 to 96 hours.

In Lubeck, 5 times 24 hours.

In Hamburg, 5 times 24 hours in winter. 4 times 24 in summer.

In Strasburg, 117 to 144 hours.

The variability in time is partly explained by the more rapid maturing of the vesicles in summer than in winter.

In Berlin, portions of the lymph collected were made into dry preparations, and the balance was prepared as an emulsion with glycerine. For this purpose Döring's lymph mill was quite generally employed. This machine is represented in Fig. 653. This preparation contains 1 part crude lymph, 2 parts glycerine, and 2 parts of distilled and sterilized water. It is quite liquid and is readily used. It settles or separates a little on standing, so that the mixture must be shaken before it is used. The separation has not resulted in any failure in practice. The machine for preparation of the lymph has usually worked well.

In Cologne, before gathering the lymph, the animals were slaughtered outside the vaccine establishment, and were then laid upon a portable stand arranged for the purpose. It consists of a trestle or frame made of wooden slats, placed in an inclined position, and hollowed out to allow the water used in cleansing to run off. Under this is a sheet of metal, also curved, which catches the water and conveys it to a receptacle which also holds the head of the animal and its blood. An iron upright at the centre and side of the frame is used to fasten the right leg of the animal. This apparatus can be cleaned easily, and needs but little repairing.

Delivery of the Lymph.—A careful record is kept at each establishment of the date of sending, quantity, recipient, and other important items. By far the greater quantities were furnished in the months of May and June. The recipients were classified into public vaccinators, private physicians, and military physicians. The former class used by far the greatest quantity of lymph.

Sending and Packing of the Lymph.—The usual mode of sending lymph from the stations in the German cities is by mail in capillary tubes, usually containing about enough for 5 vaccinations, and in large glass tubes containing 50 or 100 such portions. These are securely packed in wooden or pasteboard boxes, with directions for use accompanying them.

In most of the cities, test vaccinations were made upon calves for the purpose of proving the efficiency of the lymph before forwarding it. In times of unusual demand, however, this practice was omitted.

The Efficiency of the Vaccinations.—The results are stated with great care, both as to the number of persons vaccinated, as well as the number of insertions or separate scarifications made.

The superintendent of the vaccine establishment at Halle made 804 revaccinations, with the following results:

Number of children.	Number of vesicles.	Description of the vesicles.
418	2,371	Like those of primary vaccinations.
211	1,095	Fully developed vesicles, but in shorter time.
123	667	Producing crusts which covered the entire scarified surface.
52	306	Nodules with reddened areolæ.

In Leipzig observations were made upon 22,158 primary vaccinations, in which the successful vaccinations amounted to 21,982, or 99.21 per cent.; partially successful, 145, or 0.65 of one per cent.; and unsuccessful, 31, or 0.14 of one per cent. Of the revaccinations, 15,115 out of 16,706, or 90.48 per cent. were successful.

Duration of Efficiency.—Lymph, when carefully preserved at an even and low temperature, retained its efficiency from two to four months, and even longer.

Lymph used at stations was usually quite fresh, but private physicians often found it efficient at the age of several months. Tests were made at Stettin of lymph, 46, 81, 102, 138, 153, 175, 178, 229, and 249 days old, and in each case it was found to be efficient. The lymph was preserved in glass tubes.

Some lymph was sent to Madras from Berlin, February 17, 1891, and a calf vaccinated with this lymph on the 17th of March, had 101 good vesicles out of 121 insertions. This was also successfully transmitted from this calf to others. In some cases lymph sent to places in hot climates proved without effect.

Diseases Following Vaccination.—Vaccine physicians are instructed to make special observations upon this point. Out of the immense number of vaccinated persons in Germany, but very few cases of erysipelatous eruptions, swelling of the axillary glands, and slight skin eruptions of a temporary character were recorded, and no cases of syphilis were mentioned.

Preparation of Lymph.—The following account of the method of preparing vaccine lymph at Berlin is given by Professor Albert Guttstadt, in an article entitled "Das Impfwesen in Preussen in 1887–88," in the "Zeitschrift des Konigl. Preuss. Statistisch Bureaus, 1890."

The skin of the calf is first washed with warm soap and water. The incisions then show clearly, and the lymph is taken out with a sharp spoon, shaped like a potato-borer.

The lymph was at first mixed with glycerine in a porcelain mortar, but afterward a machine was employed which was designed by the assistant, Dr. H. Döring.

This apparatus, the "Döring Lymph-mill," is the result of several trials, and consists of an iron frame fastened to an iron plate, supporting four cylinders of porcelain having roughened surfaces. These cylinders are removable, and may be sterilized.

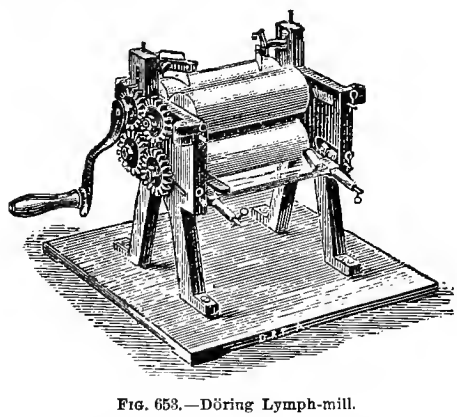

Fig. 653.—Döring Lymph-mill.

The difficulty of obtaining porcelain cylinders of regular shape necessitated careful adjustment of the iron axes. Each cylinder, therefore, must be placed in its own socket, and the axes are adjusted by springs. The slots in which the cylinders play are so arranged as to bring the cylinders into close contact.

The lymph, when introduced, passes between the cylinders, and is scraped off by a glass plate which is held against one of the lower cylinders. It then falls into a rectangular glass dish. In order to keep the lymph from spreading out at the ends of the cylinders, glass shields at each end keep the mass within bounds. The cylinders are easily removed and replaced.

The lymph is first mixed by light stirring with one-third of its weight of glycerine, and is then placed on the line of contact between the cylinders, a little at a time, while an assistant turns the handle. In a few moments the finely mixed lymph mass is scraped off from the last cylinder by the glass shield, and caught in the dish below. After the whole mass has passed through the apparatus, it is stirred with a glass rod, with the addition of more glycerine, and is passed through the mill again. It is advisable, after emptying the lymph upon the cylinders, to scrape the dish to avoid loss. The lymph is then ready for use. The loss is at the utmost 0.5 per gramme. From 20 and 25 grammes of raw

lymph may thus be easily prepared for use in thirty-five minutes.

On May 22d, there was prepared 200 grammes of raw lymph from ten calves, making in all 800 grammes of finished product in two hours.

The apparatus, exclusive of the plate in which it stands, is about twenty centimetres (eight inches) in each dimension. Accompanying each apparatus are two rectangular dishes and glass scrapers, a spatula to collect lymph, a clamp, screw-driver, and oil-can.

The apparatus is sold by Julius Schober, Adalbert Street, 39, Berlin.

In May and June the delivery of the lymph was limited almost wholly to a mixture of the product of several animals. Sometimes 2, 3, 4 or 5 animals are required, and once a mixture of the lymph of 13 animals was used.

The form of lymph used has been almost wholly the glycerine emulsion. A small quantity was employed in the form of powder. For the purpose of preservation, Erlenmeyer flasks were used, sterilized, stopped with sterilized wadding, covered with a rubber cap, and placed in a refrigerator. Just before sending out, the emulsion is put into small sterilized bottles, stopped with corks. Capillary tubes are rarely used.

In Hamburg lymph is gathered by means of forceps. It is collected on the fourth or fifth day. An emulsion is made by rubbing with a rough glass pestle in a roughened glass mortar, the proportions being one part of the raw lymph and two parts of purest glycerine. The finished product is deposited in an ice-chest.

The following simple method is employed in Hamburg for transferring the emulsion to small glass receptacles.

A thick glass tube, shaped like a glass syringe, bent, and without a piston, is employed. The cylinder is 8 ctm. in length ($3\frac{1}{5}$ in.) and 12 mm. in diameter ($\frac{1}{2}$ inch). The point is bent at an angle of about fifty degrees from the axis of the cylinder, and consists of a tube 4 ctm. ($1\frac{2}{5}$ inch) long, by 3 mm. ($\frac{1}{8}$ inch) interior diameter.

The mouth of the tube is stopped with a cotton pledget. The cylinder holds 10 gms. or more. The finger is applied to the top of the cylinder, and the emulsion allowed to flow out, the finger controlling the flow. (Fig. 654.) The hands must be disinfected, and the tube and receptacles sterilized by boiling.

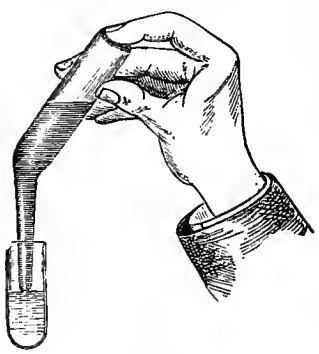

Fig. 654.

The apparatus is sold by L. Bartels, of Hamburg, Grossereichen Strasse, 67. Price, 20 pf. (5 cents) each.

In commenting upon the different forms of employing lymph Layet states three general modes of use :

1. Lymph diluted with a convenient excipient.
2. Pulp resulting from scraping or shaving the vesicles.
3. Lymph dried and reduced to a powder.

Layet does not approve of ivory points as a successful method of employment. (Nevertheless, ivory points to the number of several millions have been used for vaccination with good success in the United States, where they have constituted the chief method of using lymph since 1871.)

In describing the different modes employed in Europe Layet enumerates the following, some of which are merely experimental and but little used :

The *pâte Milanaise* is made by scraping the vesicles and the surrounding skin, and mixing the whole with glycerine in the proportion of $\frac{1}{2}$ gm. to each vesicle. This pulp should be used immediately, or within a very few days.

Reissner's powder (Darmstadt), consists of lymph dried under a bell-glass in the presence of sulphuric acid, and reduced to a powder. When used it is mixed with equal parts of glycerine and water. (For further information in regard to this powder, consult Reissner : Über eine einfache Methode zur Aufbewahrung thierischen Impfstoffs, Deutsch. Med. Woch., 1881.)

The extract of Pissin is another form of dried lymph.

The pâte and powder of Schmitt & Wolfberg, of Bonn, is a mixture of powdered lymph and dextrine dried, with or without the addition of bicarbonate of soda. Moistened with a little water it makes a syrupy mixture and it is claimed to be active for six months. (Schmitt & Wolfberg : eine Modification der Reissnerschen Methode zur Gewinnung anim. Lymphstoff, Berlin. klin. Woch., 1886.)

Vaccination in Japan.—Vaccination has made rapid progress in Japan since its introduction there. It appears from the Government reports that calf-lymph is now very largely used. The vaccine farm was at first under control of the Government, but was finally intrusted to a private association. February 16, 1888, a commission was appointed to investigate the subject of the preservation of lymph, so that it could be distributed to distant places and still be used with efficiency. This commission proceeded to the pasture-ground of Misawa Mura, reaching it March 25th, from which date their experiments were continued through the summer. The experiments were in two series, one extending over one hundred and four days, and the other for four hundred and fifteen days, and the experimenters concluded that stored lymph could be successfully used for two hundred days.

Information is not given as to the mode of preservation.

The instructions issued to the association when the work was intrusted to it, were as follows :

1. The business of the farm shall be under the control of the Director of the Sanitary Bureau.
2. The association shall not neglect to make improvement, but shall endeavor to supply good and efficient vaccine lymph.
3. The vaccine lymph shall always be stored in sufficient quantities to meet the demand.
4. The regulations of the vaccine farm shall be made by the association, and shall be reported to the Director of the Sanitary Bureau, and a similar report shall be made if they should be altered.
5. The principal of the vaccine farm shall be appointed by the association, and his appointment shall be reported to the Director of the Sanitary Bureau.
6. The price of lymph shall be fixed by the association, and shall be reported to the Director of the Sanitary Bureau, and the same shall be done if the price should be altered.

In a report upon the subject of compulsory vaccination and revaccination by Dr. E. Deschamps, before the Society of Public Medicine and Professional Hygiene, April 22, 1890, the writer sums up the advantages of animal vaccination briefly as follows :

Ease of production in unlimited quantities, good prophylactic power, and impossibility of transmitting diseases peculiar to man, and especially syphilis.

With reference to the question of the possibility of transmitting tuberculosis, he first says, that if tuberculosis is transmissible by bovine lymph, there is no reason why it should not be just as transmissible by humanized lymph.

But experiments show that the bacillus tuberculosis does not readily find its way into vaccinal lymph. L. Meyer, in 1892, examined the vaccine lymph of four tuberculous adults and found no tubercle bacilli. Experiments of Josserand in Chauveau's laboratory demonstrated that vaccine lymph from tuberculous subjects, inoculated in guinea-pigs, in the conjunctiva and peritoneum, did not produce tuberculous infection. In 1884 Strauss examined the vaccine lymph of five women well advanced with phthisis, without finding tuberculous bacilli. This lymph inoculated upon rabbits did not render them tuberculous.

In summing up the question, Dr. Deschamps con-

cludes that "Vaccination, especially when followed by revaccination, prevents the spread of small-pox.

"In countries where vaccination and revaccination are obligatory, small-pox has almost entirely disappeared.

"When performed in a proper manner, with calf-lymph, they are devoid of danger. Compulsory vaccination and revaccination should be legalized in France."

On the Preservation of Lymph in Glycerine.—Dr. Sclavo, in a paper on the preservation of different kinds of virus in glycerine, mentions the quality which glycerine possesses, of preserving the effective quality of virus for a considerable length of time. He quotes the experience of Roux and of Uffreduzzi, the latter having preserved the virus of rabies unaltered for six months.

He was induced by these facts to extend his experiments to other pathogenic bacteria and to test the effect of glycerine upon them.

Three different kinds of pathogenic bacteria were thus subjected to this experiment by Dr. Sclavo. He concluded that if later research should confirm his experiments and prove that glycerine has the power of preserving the vitality of other micro-organisms, the bacteriologist would thus have a preservative which might serve to maintain some of the germs which, like the diplococcus of Fraenkel, rapidly lose their vitality in the ordinary culture media. This property would prove an efficient aid when it should be necessary to transport pathogenic virus from one place to another for purposes of study and experiment.

Dr. Deschamps, in an article in the *Revue d'Hygiene*, August, 1892, relates an instance in which M. Trapp and Dr. Kireger were experimenting with vaccine lymph in Strasburg, in 1876. The latter put some glycerinated lymph into a vial closed by means of a pledget of cotton. This vial was mislaid in a closet, and was not found again until M. Trapp found it in 1887, eleven years after. Meanwhile the closet had been exposed to extremes of temperature in summer and winter. The contents of the vial remained unchanged.

The lymph was used to vaccinate a calf, and produced normal pustules.

Dr. Deschamps quotes the advice of several prominent vaccinators as to the period during which glycerined lymph should be used. Le Clerc, Deutl, Vallin, Warlomont, Vaillard, and Mangenot give different periods, from eight days to several months.

Chambon and St. Yves Menard have sent their preserved lymph to many distant countries—Madagascar, North and South America, Brazil, the West Indies, and the islands of the Pacific, in some of which it was used successfully, where the heat was 135° F. in the sun and 90° F. in the shade. Dr. Deschamps concludes that this form of prepared lymph can be safely used during the six months after its collection, and preserves its efficiency during that time.

Bacteriological Investigations.—The following brief summary presents the principal points relating to the bacteriology of vaccine lymph:

Cohn distinguished, under the name of the vaccine micrococcus, round bacteria, united together in chains or little rolls, which he observed in the lymph of vaccine vesicles (*Virchow's Archiv*, 1872).

Quist, of Helsingfors, made a culture of vaccine in serum of beef with glycerine. At the end of eight or ten days a thin pellicle of micrococci had formed. A child inoculated with this culture had a true vaccine vesicle, with immunity against revaccination. This experiment was not confirmed (*St. Petersburg Med. Woch.*, 1883).

Ferré detected in vaccine lymph a peculiar microbe, rounded or crescent-shaped, very movable, and provided with two little projections on opposite sides. A similar microbe has been described by Professor Jolyet, of Bordeaux (*Revue Sanit. de Bordeaux*, 1873).

Voigt mentions three species of micrococcus, one liquefying gelatine, another non-liquefying, and still another having no special characteristics (*Deutsch. Med. Woch.*, 1885).

Bauer found in vaccine lymph, besides other ill-defined organisms, spherococci, solitary or disposed in groups of two or four, or in the shape of little chains. The groups of four appear in fresh lymph, and the chains in old lymph (*Centralblatt für d. Ges. Therapie*, 1885).

Other observers (German and Italian, in 1886 and 1887), Tenhot, Garré, and Marotta, claimed the discovery of certain micro-organisms in vaccine. Garré succeeded in producing good vesicles in the calf and immunity, but was not able to produce them in man (*Deutsch. Med. Woch.*, 1887).

Pfeiffer found in vaccine lymph a fungus which he called *saccharomyces vaccinæ*, also the sarcina lutea and s. anrantiaca, common in air, and micrococcus pyogenes aureus and *cereus albus*.

For several years the Grocers' Company of London has offered a prize of £1,000 ($5,000) to any one who should discover a method of culture of vaccine outside the living animal organism. Patient investigators are busily employed with this end in view. In commenting upon this inducement, Professor Layet says: "C'est là un sérieux stimulant, mais nous doutons fort que quels que soient le microbe reconnu spécifique et les procédés de culture employés, on puisse jamais reproduire la substance vaccinale chimique qui seule s'élabore au sein des tissus vivants dans la zône lymphogène de la pustule."

Analysis of vaccine lymph to determine its physical properties.

Messrs. Schulz and Weyl, contribute to *Koch's Zeitschrift für Hygiene* the following:

Analysis of Reissner's lymph powder: A portion weighing 2.95 gm. was examined, and found to be a colorless, partially powdered, and filamentous mass. It was ground fine in an agate mortar, and one part (0.924 gm.) was dried at 105° C.

The second part (1.903 gm.) was boiled in 200 c.c. of absolute alcohol for two hours. The residuum was treated for two hours more in the same manner and evaporated at 80° C.

The following was the result of the analysis:

Reissner's Lymph Powder.

	Containing water, per cent.	Water free, per cent.
Water	10.22	.....
Ash	4.7	5.2
Ash, soluble	12.6	12.6
Ash, insoluble	87.3	87.3
Alcohol extract	2.5	2.8
Ether extract	35.3	39.35
Insoluble tissue	47.28	52.65

The amount of ether extractive is noteworthy. An experiment with dialysed lymph inoculated upon three children, and also upon calves, was without any result.

Another experiment was made in which lymph was filtered through a Chamberland filter. The product was clear, colorless, and germ-free.

Humanized and bovine lymph were both filtered in this manner, and the filtrate inoculated upon children and calves without result, proving that the efficiency of vaccine lymph is due to germs which cannot be filtered through.

Experiments in Immunity.—Certain experiments in vaccination by Strauss, Chambon, and Menard are detailed in the "Transactions of the Soc. de Biologie," December 20, 1890 (*Compt. Rendus*, "Soc. de Biolog.," 1890, p. 721), of which the following brief summary is presented:

1. Inoculation of vaccine lymph upon the cornea of a calf produced intense iritis with opacity of the cornea. Immunity also resulted in the case of this animal.

2. Intravenous injection of vaccine lymph into the jugular vein also produced immunity in another animal.

3. Transfusion of one thousand grammes of the blood of a calf at the time of the height of the vaccine eruption into another calf gave negative results. The second calf was found capable of contracting cow-pox.

4. Injection of sixty grammes of the blood of a calf at the full eruption of vaccinia was made under the skin of

another calf without results. This second calf was afterward successfully vaccinated.

5. Transfusion of the blood of a calf having vaccinal immunity into another unvaccinated calf. This experiment demonstrated that almost all of the blood (*la presque totalité*) of a calf having vaccinal immunity might be transfused into an unvaccinated calf without producing immunity in the latter.

6. An experiment in which filtered vaccine lymph was subcutaneously inoculated into a calf showed that immunity was not conferred by this process.

Alleged Harmful Results of Vaccination.—At least seven hundred thousand vaccinations were performed in England and Wales in 1888, according to the Report of the Local Government Board upon that year, and in the course of the year representations were received by the Board from ten sources, alleging injury of one or another kind to have resulted from vaccination. Inquiry showed that two of these cases were measles and whooping-cough concurrent with vaccination, two were skin eruptions following vaccination, and the remainder were cases of erysipelas or similar disease.

Mr. Jonathan Hutchinson, a member of the Royal Commission upon Vaccination, and an acknowledged authority upon the subject of vaccinal eruptions, stated that although three-quarters of a million vaccinations have been made annually for several years, the Local Government Board had not found a single instance of syphilitic communication by means of vaccination (*Lancet*, i., 1891, p. 204).

At the annual meeting of the British Medical Association at Birmingham, in 1890, Dr. Malcolm Morris read a paper upon the subject of vaccination eruptions in which he presented the following conclusions :

1. That pure calf-lymph should be used when possible.

2. That it is desirable that vaccination should be performed in children not later than six weeks after their birth.

3. That strict antiseptic and protective treatment should be carried out immediately the vesicles have developed.

4. That the cases should be seen by the vaccinator until the wounds have healed.

5. That eczema, psoriasis, and other skin diseases should be treated immediately they appear.

A full discussion of the subject endorsed the foregoing conclusions (*Brit. Med. Jour.*, 1890, ii., 1229).

The British Parliamentry Commission of 1889.—From the very beginning of the introduction of vaccination opposition has been manifested to its practice, the degree of resistance differing much in different countries. In England several Parliamentary inquiries have been held upon the subject, the general result of which has been a confirmation and strengthening of existing laws upon vaccination. The last Parliamentary Commission appointed to consider this subject was that of 1889, and this commission has not yet reported in full. The commission consists of fifteen members, of which Lord Herschel is chairman. It has published several reports of evidence but no final conclusions. One interim report (1892) relates entirely to the question of repeated penalties and the treatment of prisoners under the Vaccination Acts. Many witnesses have been examined by this commission, including such noted experts as Sir John Simon, Dr. Ogle, of the Registrar-General's Office ; Dr. Buchanan, Dr. Thorne Thorne, Dr. Corey, Dr. Barry, and other officials of the Local Government Board of England. The principal advocates of repeal of the compulsory laws were Alfred Russell Wallace, LL.D., Messrs. Alexander Wheeler, William Tebb, and others.

The points which this Commission was charged to consider were the following :

1. The effect of vaccination in reducing the prevalence of, and mortality from, small-pox.

2. What means, other than vaccination, can be used for diminishing the prevalence of small-pox, and how far such means could be relied on in place of vaccination ?

3. The objections made to vaccination on the ground of injurious effects alleged to result therefrom ; and the nature and extent of any injurious effects which do, in fact, so result.

4. Whether any, and if so, what means should be adopted for preventing or lessening the ill effects, if any, resulting from vaccination ; and whether, and if so, by what means, vaccination with animal vaccine should be further facilitated as a part of public vaccination.

5. Whether any alterations should be made in the arrangements and proceedings for securing the performance of vaccination, and, in particular, in the provisions of the Vaccination Acts with respect to prosecutions for non-compliance with the law.

At the time of making its brief interim report, April 21, 1892, the Commission had held ninety meetings and examined one hundred and thirty-five witnesses, and had not then completed the evidence upon any one of the points to be considered. The two recommendations which it has made were substantially as follows :

1. It appears that the Courts had so construed the laws as to warrant repeated orders in respect to the non-vaccination of a child and the imposition of a penalty for the disobedience of each of such orders, notwithstanding that previous penalties have been inflicted. The Commission agreed that the imposition of repeated penalties in respect to the non-vaccination of the same child should no longer be possible. They arrived at this conclusion independently of the question whether vaccination should continue to be compulsorily enforced.

Those who favored the view that vaccination ought not to be compulsory were naturally opposed to repeated convictions ; while those who inclined to the opposite view believed that any advantage which could arise from the tendency of repeated convictions to increase the number of the vaccinated, is more than counterbalanced by the resentment and active opposition to vaccination which they engender.

2. The question having arisen whether a person committed to prison on account of failure to pay the penalty imposed under the Vaccination Laws, should be treated as a criminal or not, the Commission expressed its opinion that such persons "should no longer be subjected to the same treatment as criminals. Many of the victims of such imprisonment regard the practice of vaccination as likely to be injurious to the health of their children, and are well-conducted and in other respects law-abiding citizens. Even those who consider that the course which such persons adopt is a mistaken one, may nevertheless well be of the opinion that they ought not, during their imprisonment, to be subjected to the treatment awarded to criminals, such a proceeding not being calculated to secure obedience to the law or to add to the numbers of the vaccinated."

Dr. Alfred Russell Wallace appeared before the Royal Vaccination Commission, in 1890, as a convert to the principles of anti-vaccination, and was hailed by the opponents of vaccination with great triumph. Dr. Wallace confidently expected to demolish the arguments in favor of vaccination upon scientific principles, and appeared before the Commission with a long array of tables of statistics and diagrams which fill many pages in the Third Report of the Commission. The principal part of these statistics relates to vaccination in the departments of France for a period of about twenty years. The data presented for each department are the number of births, number of vaccinations, and number of deaths from small-pox for each year, the object being to show that vaccination increases small-pox.

These tables were taken up and carefully considered by the Commission, and, so far as Dr. Wallace's hasty conclusions were concerned, they were found to be absolutely worthless. This witness finally admitted, after retreating step by step, that his tables were "not perfect," that "the imperfection is very great and irregular." He also admitted that, if his entry of "no deaths" often meant nothing more than that there had been "no returns" (which was actually the case), "then, of course, the whole thing is imperfect," and that in view of such

a defect, which was vitally important, "the whole thing is valueless."

Criticism followed upon criticism, and at last Dr. Wallace asked that he might make a few personal concluding remarks, the pith of which had to do with suggestions from the Commission that he must have "taken up this subject and written upon it without full and accurate information befitting a man of science." And, in making the personal explanation, the previous declarations as to the absolute need for a scientific accuracy such as had controlled the labors of Darwin seems to have been forgotten, and in their place came the frank admission, "My answer is that I did not take it up as a question of pure science."

Thus ended the "absolute test and demonstration" held out at the previous session of the Commission, and the result is that the opponents of vaccination still lack a scientific statistician as an exponent of their views (editorial in *Practitioner*, 1891, vol. xlvi., p. 465).

The small-pox statistics of Prussia, which Dr. Wallace presented to the Commission, were brought down to the year 1874, and there discontinued. The compulsory law of Prussia was enacted in 1874, and Dr. Wallace admitted that "he had heard of it," but had not seen any evidence that it made any important difference.

On the contrary, there are nowhere to be found any statistics so absolutely conclusive of the value of vaccination as the comparative statistics of Prussia for the two periods before and after the enactment of the compulsory vaccination law of 1874.

The London *Lancet*, in commenting upon the testimony of this witness, says that Dr. Wallace's theory was based upon "blunders that would hardly be expected of a school-boy," and in a concluding paragraph upon the same subject affirms, "if this is all that science can do for the anti-vaccinationists, the scientific value of vaccination stands more than ever confirmed."

In commenting upon this Fifth Report of the Parliamentary Commission a well-known English physician (Dr. Dudfield) says: "It is to be regretted that at a time when, as we have seen, small-pox threatens to assume an epidemic form, a retrograde step should have been taken by the Royal Commission which is not unlikely to be attended with disastrous results, by encouraging disobedience to the law in respect of vaccination, the only, and all but specific, protection against the most loathsome of diseases."

With reference to the interim recommendation of the Commission, Dr. Dudfield further says: "Exemption from the operation of the compulsory vaccination law (and incidentally the power to spread disease, deformity, and death among the community) would be purchaseable at the cost of one pound sterling—to be paid, doubtless, by anti-vaccination societies."

It appears that the previous Commission of 1871 had made a recommendation of similar character, which was rejected by Parliament. "Whatever the decision of the Government, or of Parliament acting independently, in this question, it must surely be felt that the recommendation of the Commission is ill-timed; and, should small-pox become epidemic, may prove disastrous.

"There is only one consolation in view of this contingency, and it is that people who reject the boon of vaccination, when they have no fear of small-pox, very commonly hasten to secure its protection when the disease is prevalent, if indeed they are not, as often happens, already protected. This applies most, perhaps, in the case of the well-informed among the anti-vaccinators, the brunt of the epidemic usually falling on the poor and ignorant."

Leicester has been quoted by the opponents of vaccination as a large non-vaccinating town. (The children "unaccounted for" in the vaccination returns of Leicester, for 1883 to 1887, were 56.9 per cent. of the births, as compared with only six per cent. for all England and Wales for the same period.) "It can hardly be doubted, however, that a time will come when all the admirable precautions taken at Leicester will prove unavailing, and that its rulers will have cause to regret their disregard of Jenner's beneficent discovery, which, with a minimum of risk, which might be avoided by the use of calf lymph, has conferred incalculable benefit in every civilized community in the world, and just in proportion to the efficiency with which it has been applied."

The principal modern opponents of vaccination who have published their views upon the subject, are Professor E. M. Crookshank, Dr. Charles Creighton, Mr. William Tebb, Professor A. Vogt, of Berne, and Lorinser, of Vienna.

Dr. Creighton's views upon vaccination are sufficiently set forth in his article in the twenty-fourth volume of the "Encyclopædia Britannica," and in his book entitled "Cow-pox and Vaccinal Syphilis." In the former he takes the ground that there is neither identity nor even affinity between vaccinia and variola. He also asserts his belief that the diminished activity of variola is due to epidemiological laws, and not to vaccination. In his exceedingly superficial statement of the practical working of vaccination laws, like Dr. Wallace, he omits reference to the convincing experience of Prussia since the enactment of more efficient laws in 1874, although a dozen years or more had elapsed from that date to the publication of his article in the "British Encyclopædia."

The various publications issued by the opponents of vaccination are characterized mainly by the absence of facts, and the presentation of an abundance of theory. For example, a recent work by Mr. William Tebb, intended to prove the "synchronicity between the spread of leprosy and vaccination," introduces many arguments in support of an alleged connection between the one and the other. But leprosy produced its most disastrous effects in the twelfth, thirteenth, and fourteenth centuries, when vaccination was unknown. There were then 19,000 lazarettos in Europe. Now that the human race is much more widely distributed over the globe, leprosy is far more rare, and exists to its greatest extent in countries where vaccination is but little practised. In the United States, where probably more than three-fourths of the population is vaccinated, leprosy is confined chiefly to a very small number, among whom the disease was introduced directly from other and infected countries.

Leprosy has for many years been prevalent in Bombay, but since the introduction of vaccination there, by the British Government, the ratio of lepers has gradually diminished. The census of 1871 showed that the ratio of lepers was 8.5 per 10,000 of the population. In 1881, it was 6.1, and in 1891, only 5.3 per 10,000. The *Sanitary Record*, June 15, 1893, in commenting upon this fact very justly says: "This certainly does not indicate that there is any necessary connection between the appearance of leprosy and the practice of vaccination, unless it be that the latter is the cause of the decrease of the former. There seems to be no reasonable ground for alarm about an alleged recrudescence of leprosy."

One of the most notable publications of the past decade upon the subject of vaccination is that of Professor E. M. Crookshank, entitled "The History and Pathology of Vaccination," two volumes.

The chief value of this publication lies in the collecting together of many of the early English writings upon the subject in the second volume of the work. Jenner's original essays are here republished, together with those of Ceeley, Badcock, Estlin, Auzias-Turenne, and others.

The author himself opposes vaccination mainly upon theoretical grounds; of the practical operation of vaccination in civilized countries, he has very little to say.

He avows his belief that variola and vaccinia are entirely distinct diseases, having no relation to each other. In commenting on Ceeley's and Badcock's experiments, the latter having successfully inoculated thirty-three out of two hundred cows with small-pox lymph, and furnished lymph to four hundred practitioners for use in vaccinating fourteen thousand people, Professor Crookshank explains the matter by saying that these people were not vaccinated, but "variolated." What, then, prevented these people from spreading small-pox by infection? Professor Crookshank advocates the inoculation of

nurses in small-pox hospitals with "attenuated" variolous lymph, but advocates notification and isolation everywhere else as the chief measures of prevention.

RECENT LEGISLATION RELATIVE TO VACCINATION.—No very great or decided changes have been made in the vaccination laws of the principal civilized countries during the past five years. Public vaccination has been encouraged by the establishment of vaccinal institutes for the propagation or production of bovine lymph.

In the main, the tendency of civilized governments has been toward increasing stringency in the matter of compulsion, and at the same time a greater use of calf lymph as compared with humanized lymph.

Attempts were made to repeal the compulsory law in Holland in 1890, but without success. A meeting was held at Utrecht September 7, 1890, at which the directors of the various vaccine establishments of Holland opposed the repeal of the law. (*Practitioner*, 1890, p. 470.)

A fresh departure has been taken by the Italian Government, and the new law of Italy, adopted in 1891, is herewith presented in full.

MINISTRY OF THE INTERIOR.
DEPARTMENT OF PUBLIC HEALTH.

Special Regulations as to the Preservation of Lymph and Compulsory Vaccination.

The Secretary of State for the Interior having regard to Articles 51, 52, 53, and 62 of the Law for the "Protection of Hygiene and Public Health," after consultation with the Board of Health, decrees that these consolidated Special Regulations as to the preservation of Lymph and Compulsory Vaccination have received his approval.

G. NICOTERA,
Home Minister.

ROME, June 18, 1891.

Special Regulations for the Preservation of Lymph and for Compulsory Vaccination.

I. PRESERVATION OF LYMPH.—Article 1. By the terms of article 52 of the law for the Protection of Hygiene and Public Health, the lymph shall be preserved by the medical officer of the administrative sanitary authority for the province under the direct supervision of that authority, and the expenses incident thereto shall be charged to the province.

Article 2. The provincial authorities are empowered to preserve and provide both animal and humanized lymph to the communal authorities and to private medical practitioners.

Article 3. Animal lymph may be preserved by the aforesaid medical officer of the province, either at an institute for the production of lymph established by the provincial authority, or at an existing private institute for the production of lymph which has received official recognition from the provincial authority. In either case the institute must be put under the supervision of the medical officer. The medical officer is also empowered to make use of the National Vaccine Establishment at the office of the Department of Public Health (in Rome).

Article 4. The provincial authorities desirous of establishing an institute for the preservation and production of animal lymph, must take care to provide premises with proper stabling for the animals to be inoculated, and with suitable accommodation for the process of inoculation and the collection, preparation, and preservation of vaccine.

Article 5. The provincial authorities who desire to give official recognition to an already existing private institute shall, before giving their recognition, obtain a written certificate from the medical officer of the province, to the effect that the institute fulfils the requirements as to the premises and staff referred to in the preceding article, and that it can produce vaccine of good quality and sufficient in amount to meet the wants of the locality.

Article 6. By-laws, approved by the prefect after consultation with the medical officer of health of the province, will regulate the administration of the institute, whether established by the provincial authority or merely recognized by it, setting out the technical rules and administrative principles of its management.

Article 7. The provincial authorities desirous of making use of humanized lymph shall provide the requisite staff, premises, and materials, according to the instructions given for that purpose by the medical officer of the province.

The same officer shall supervise, or cause to be supervised, the selection of children from whom the lymph is to be obtained, and shall see that proper precautions are taken to insure a good quality of lymph and its perfect preservation.

Article 8. The provincial authorities who intend to obtain animal lymph from a private institute, or from the National Establishment in Rome, shall intrust to a specially selected sanitary inspector the duty of obtaining and distributing the lymph according to local requirements, and of supervising its use in the interests of the province. This officer is also required to collect the statistics of vaccination and small-pox in the several communes of the province, according to the reports to be furnished to him by the sanitary officials of the communes (see Articles 19–22).

Article 9. The said sanitary inspector, who shall act as the representative of the province in matters of vaccination, shall be nominated by the Prefect after consultation with the provincial board of health, and shall receive a salary from the funds of the province proportionate to the importance of his work, and officially his post shall be subordinate to that of the medical officer of the province.

Article 10. The procedure to be followed in obtaining the lymph from the National Vaccine Establishment, and in reimbursing out of the provincial funds the cost to the treasury, is set out in the instructions contained in the memorandum of the Department of Public Health to the Ministry of the Interior.

II. VACCINATION.—Article 11. By the terms of Articles 51 and 52 of the law for the protection of hygiene and public health, it behooves the communal authority in every contingency to provide for the vaccination of all inhabitants within their area, and to take care that the obligation to undergo this practical prophylactic treatment, which has been imposed by the law, is respected by all, according to the instructions in these regulations.

Article 12. The sanitary regulations for the commune shall impose the responsibility for the observance of this legal obligation upon the parents (or their representatives) of all children born in the commune till they are of age.

Article 13. All children must be vaccinated within the solar half-year subsequent to the date of their birth (see Article 18), with the exception :

(1) Of such children as have in the meanwhile been attacked by small-pox.

(2) Of children with regard to whom a medical certificate can be produced, to the effect that they are in such a state of health as renders it dangerous for them to undergo the operation of vaccination.

Article 14. Children who, owing to ill-health, were exempted from vaccination during their first year of life, must be submitted for vaccination during their second year.

In cases where there may be doubt as to whether a child can be safely vaccinated, the official vaccinator must decide upon the case after having first himself examined the child.

Article 15. Children who have been vaccinated for the first time without showing favorable results, must be again vaccinated at the latest within the ensuing year, and this repeated vaccination must be performed by the official vaccinator.

Article 16. After the age above referred to every individual must offer himself for revaccination whenever the sanitary authority considers that, owing to the existence of special danger of epidemic, such revaccination is necessary.

Article 17. No child can be admitted into a public or private school, or to public examinations, or into any educational or benevolent institution, public or private,

or into any factory or workshop of any kind, if, being eleven years of age or older, he cannot produce an authentic certificate from the communal authority to the effect that he has been revaccinated since he reached eight years of age.

The directors of schools, institutions, factories, or workshops, or whoever may be at the head of any body of persons having the supervision of children of any age above that of eleven, must be held responsible for the observance of this regulation.

Such persons must also take care that all children between the age of ten and eleven that are likely to remain under their supervision are revaccinated according to the requirements of law.

The persons designated must at every request of the communal authority, show the certificates of revaccination of the children intrusted to them.

Article 18. In every commune there shall be annually two gratuitous public vaccinations, one in each solar half-year, at such period as shall be considered best to facilitate the largest attendance of children.

There shall be extraordinary gratuitous public vaccinations wherever it is held that such extraordinary vaccinations are necessary for the more complete observance of law, or where, owing to the appearance of cases of small-pox in the commune, there may be danger of the spread of the disease.

Article 19. The communal authority shall in all cases provide the necessary funds to maintain a staff of sanitary officials (physicians and surgeons) sufficient to vaccinate gratuitously all the individuals who are to be vaccinated, whether the obligation to undergo this operation is due to legal requirements or to the ordinances of the communal or superior government authorities.

Article 20. All persons who have been vaccinated shall present themselves or be presented for vaccination to the official vaccinator, between the seventh and tenth days after vaccination, and the official vaccinator shall himself report, for the purpose of registration to the communal authority, the vaccinations which have been performed and their results, whether the operations were performed at the public gratuitous vaccinations or by private medical practitioners.

This report of the official shall set out the Christian and surname of the person vaccinated, the date of birth, and state whether the vaccination satisfied legal requirements, or whether there is need for it to be repeated.

Article 21. The sanitary officials shall, at the end of each half-year, verify whether all the persons born in the preceding half-year have been successfully vaccinated, and in cases where there has been default it is the duty of the sanitary officials to move the communal authority to intervene according to the provisions of the law.

Article 22. The same sanitary official shall communicate to the prefect of the province, during the month of January in each year, a list of all the vaccinations that have been performed, carefully distinguishing between the cases of vaccination and revaccination.

Article 23. Certificates setting out the particulars of vaccinations entered in the registers of the communal authority, shall be granted by that authority gratuitously.

Article 24. These regulations, in so far as they have reference to the preservation of lymph by the provincial authority, the registration of all cases of vaccinations by the communal authority, and the granting gratuitously of certificates by that authority, shall come into force on the 1st day of January, 1892.

In the seventh volume of the REFERENCE HANDBOOK a digest was presented of the legislation of the principal States of the Union with reference to vaccination.

Careful inquiry shows that but few changes have been made in these laws since 1886.

The following comprise the principal modifications:

Maine.—Chapter 213, Laws of 1889. An Act to provide against the danger of the spread of Small-pox from Paper Mills.

Section 1. No owner, agent, or superintendent of any paper mill where domestic or foreign rags are used in the manufacture of paper shall hire or admit any person to work in or about said mill who has not been successfully vaccinated or revaccinated within two years, or to the satisfaction of the local board of health.

Sec. 2. No person shall work in or about any paper mill where rags are used, who has not been successfully vaccinated or revaccinated within two years, or to the satisfaction of the local board of health.

Sec. 3. The owner, agent, and superintendent in every paper mill where rags are used, shall every year, in the months of February and September, make out and deliver to the local board of health a list containing the names, ages, kind of work, and places of residence of all persons employed in or about said mill.

Sec. 4. In the months of March and October, annually, each and every person who is employed in a paper mill, shall be examined by the local board of health as to whether he or she is successfully and sufficiently protected by vaccination, and the local board of health shall in all cases be the judges of the sufficiency of the protection by vaccination.

Sec. 5. Any person who shall violate any of the provisions of this act shall be guilty of a misdemeanor, and upon conviction thereof shall be subject to a fine of not more than fifty dollars.

Sec. 6. It shall be the duty of the local boards of health within their respective jurisdictions, and of the State board of health, to enforce this act as far as comes within their power, and when said State board of health knows or has reason to believe that any penalty or forfeiture has been incurred by reason of neglect to comply with said act, it shall, at its discretion, give notice thereof, in writing, to the county attorney of the county in which said penalty or forfeiture has occurred, and upon receipt of such notice the county attorney shall prosecute the defaulting person or persons.

Approved February 23, 1889.

Florida.—As a result of a recent invasion of yellow fever, Florida established a State Board of Health in 1889, and entrusted the board with the general sanitary administration of the State. In the same year the board adopted certain regulations in regard to vaccination as a part of the sanitary code. They are as follows:

Section 11. It is hereby made the duty of the Common Council, Board of Aldermen, or other officers of a chartered city or town in this State, to provide for the vaccination and revaccination of the citizens residing in their several cities and towns. And it is also made the duty of every parent, guardian, or other person charged with the care of, or responsibility for, any child, to see that said child is vaccinated, and to have said child or children vaccinated as often as the health authorities of a city or town, or county board of health in the State may direct: *Provided*, That the requirements of this section need not be enforced in sparsely settled communities in this State except in a threatened epidemic from small-pox. *And provided further*, In any case, in the judgment of a reputable physician expressed in writing, such vaccination would be dangerous to the health of the person required to be vaccinated, such vaccination will not be required to be made. Fresh bovine virus only should be used in vaccinating in this State.

Sec. 12. After October 1, 1889, superintendents of all institutions of learning, and all school boards and principals of schools in this State, in incorporated cities and towns of over two thousand inhabitants, are forbidden to admit as a pupil any child or person who cannot produce satisfactory evidence of having been successfully vaccinated.

Sec. 13. No owner or manager of any manufactory in this State shall admit for employment any person who cannot produce satisfactory evidence of having been successfully vaccinated.

In *Vermont*, where a State Board of Health was first established in 1886, the following law relative to vaccination was enacted in November, 1892, being Section 5 of "An Act defining the duties and powers of State and Local Boards of Health, Health Officers, and others."

Section 5. It shall be the duty of every local board of health to report to the secretary of the State board of

health every case of small-pox, varioloid, Asiatic cholera, typhus fever, or yellow fever, occurring within its jurisdiction; to provide, whenever it is deemed necessary by the State board of health, a suitable supply of vaccine virus of a quality and from a source approved by said State board of health; and during the existence of an actual outbreak of small-pox in any town or city, the local board of health shall at all times provide thorough and safe vaccination for all persons within its jurisdiction who may need the same.

California.—The following recent legislation in California became operative in 1889:

An Act to encourage and provide for a general vaccination in the State of California.

Section 1. The trustees of the several common school districts in this State, and boards of common school government in the several cities and towns, are directed to exclude from the benefits of the common schools therein any child or any person who has not been vaccinated, until such time when said child or person shall be successfully vaccinated; *provided*, that any practising and licensed physician may certify that the child or person has used due diligence and cannot be vaccinated so as to produce a successful vaccination, whereupon such child or person shall be excepted from the operation of this Act.

Sec. 2. The trustees or local boards, annually, or at such special times to be stated by the State Board of Health, must give at least ten days' warning by posting a notice in two or more public or conspicuous places within their jurisdiction, that provision has been made for the vaccination of any child of suitable age who may desire to attend the common schools, and whose parents or guardians are pecuniarily or otherwise unable to procure vaccination for such child.

Sec. 3. The said trustees or board must, within sixty days after the passage of this Act, and every year thereafter, ascertain the number of children or persons in their respective school districts, or subdivision of the city school government, being of an age suitable to attend common schools, who have not been already vaccinated, and make a list of the names of all such children or persons. It also shall be the duty of said trustees or board to provide, for the vaccination of all such children or persons in their respective school districts, a good and reliable vaccine virus wherewith to vaccinate such children or persons who have not been vaccinated. And when so vaccinated to give a certificate of vaccination, which certificate shall be evidence thereof for the purpose of complying with Section 1.

Sec. 4. The necessary expenses incurred by the provisions of this Act shall be paid out of the common school moneys apportioned to the district, city, or town. And if there be not sufficient money, the trustees must notify the board of supervisors of the amount of money necessary, and the board must, at the time of levying the county tax, levy a tax upon the taxable property in the district sufficient to raise the amount needed. The rate of taxation is ascertained by deducting fifteen per cent. for delinquencies from the assessment, and the rate must be based upon the remainder. The tax so levied must be computed and entered upon the assessment roll by the county auditor, and collected at the same time and in the same manner as State and county taxes, and when collected shall be paid into the county treasury for the use of the district.

Sec. 5. The trustees of the several school districts of this State are hereby required to include in their annual report, and report to the secretary of the State Board of Health, the number in their several districts, between the ages of five and seventeen years, who are vaccinated and the number unvaccinated.

VETERINARY SCIENCE IN ITS RELATIONS TO PUBLIC HEALTH.—Modern medicine involves something more than visiting the bedside of a sick person, diagnosing the disease, writing a prescription for the relief of the patient, and leaving a few general orders regarding the administering of medicine and care of the unfortunate one. How to prevent disease is a question fully as important, if not more important, than how to cure, or attempt to cure, an illness; and every physician should pay at least some attention to preventive medicine or sanitary science; and in a consideration of this subject the communicable diseases of our domestic animals, communicable from them to man, are well worthy of the investigation that the danger from them demands. In the writer's opinion every State board of health, and the health boards of our larger cities, should have as one of its members a skilled veterinarian, or, if not as a member, it should at least have one, or if necessary more, as employees, whose duty it should be to investigate, and as far as possible suppress, all cases of infectious disease among animals common to them and mankind.

At present, in nearly all of our cities and towns there is, as a rule, one or more members of the medical profession upon the board of health, and if the services of a competent veterinary surgeon are not readily accessible, it is highly important that the medical officer should have a knowledge of the diseases communicable from animals to man, with an idea of their diagnosis, post-mortem appearance, and the steps to take for their suppression. The more important of the infectious maladies of animals, common to them and man, include actinomycosis, tuberculosis, glanders and farcy, rabies, and

anthrax, as well as vaccinia, although, as far as its danger is concerned, the latter affection is of little significance. The three first-mentioned disorders resemble each other in many ways, and may be classified as a group having many characteristics in common, known as the "infective granulomata."

The "infective granulomata" include beside actinomycosis, tuberculosis, and glanders and farcy, syphilis and leprosy; it is plain therefore that of the five diseases comprising this group, three, or a majority, are common to animals and man—one of them, glanders, being an essentially equine affection, communicable from the horse and ass to others of their own species, and from them to the human subject.

Anthrax and rabies, although not so constantly met with as the infective granulomata, may be very dangerous and cause many fatalities when they do occur.

In a consideration of these diseases the first group will be briefly described in the order already written, after which rabies and anthrax will have some of their characteristics specified.

Actinomycosis.—It is only within a few years that this disorder has been recognized as a distinct disease; Bollinger, a European veterinarian, first described it as occurring in cattle in 1877, and called it actinomycosis, on account of a fungus, the actinomyces, found to inhabit this lesion; a uniform conception of the nature of the disease was then formed by the veterinarians of all lands, and the definition and name, as given to it by Bollinger, was generally adopted.

Ponfick, in 1879, was the first to describe actinomycosis in man, although the disease had been observed by Israel, and described by him as chronic pyæmia, one year previous. And as early as 1845 Langenbeck also described a case that was unquestionably actinomycosis.

Prior to Bollinger's investigations, different authorities expressed most diverse opinions concerning it, and in cattle the affection was designated as "osteo-sarcoma," "cancer," "scrofula," "tuberculosis," "osteo-porosis," "fungoid stomatitis," "sarcomatitis," and the like, the name depending upon the location and general appearance of the growth in many instances. Some authors looked upon it as a variety of glanders peculiar to the ox tribe.

This malady, when it occurs among bovines, is commonly spoken of as "swelled head," or "big jaw," when it attacks the jaw bones; it is also termed "wooden tongue," when the tongue is affected, as it renders it hard and gives rise to a woodeny condition of that organ. Actinomycosis is most commonly seen in cattle; it may also occur in swine; cases are recorded where it has been observed in man, and in a very few rare instances the horse has been known to have it.

It has been classed with the infective granulomata, as it results in the formation of granulation tissue; this is accompanied with the formation of fibrous tissue and suppuration.

Actinomycosis is a progressive inflammatory affection, set up by a certain fungus, the *actinomyces;* this fungus belongs to the *hyphomycetes,* or moulds. It has been observed in the animals just mentioned as the result of natural infection, and has also been produced in cattle, rabbits, and other small animals by inoculation experiments. The parasite which causes the disorder is a peculiar fungus: microscopically it first appears as a tufted rosette of radiating, pyriform, or club-shaped structures; these are either single, or divided by dissepiments, and are of considerable bulk. These club-shaped structures are possibly the conidia (spores). The fungus (still microscopically) appears as a peculiar gland-like body, with the outward form of a mulberry; this appearance is produced by the aggregation of the club-shaped conidia; these spring in all directions from a matted tuft, which may be called the mycelia, and are thus crowded into a compact mass.

When the actinomyces settles in a tissue it at once sets up an inflammation in its neighborhood. While the spore is developing its mycelium and bunch of conidia, a nodular inflammatory focus is formed around it, which in its structure exactly resembles a tuberculous nodule, that is, it contains round, epithelioid, and giant cells. Recent nodules consist chiefly of round cells; older ones, at the part in contact with the fungus core, have the epithelium-like and giant cells present. The fungus core is generally yellowish in tint, and later in the process is often calcified.

When the nodules increase greatly in number and become confluent, the internodular inflammation also extending, large areas of inflammatory swelling are formed, and in many cases, especially in cattle, scar-like bands of fibrous tissue may be formed in the spaces between the nodules. The nodules themselves usually break down and suppurate, or if the tendency toward further development be strong enough, instead of suppuration large nodular patches of new tissue may be formed. These may grow for weeks or months, until they become large tumors. The tumor is made up partly of coarse fibrous tissue, partly of granulations, with the intermediate stages. It always contains small pus-cavities and other excavations, in which the fungus cores are found as small white or yellow, greasy-appearing masses lying among the purulent detritus. The small white or yellow specks are found upon microscopic examination to be clumps of the actinomyces. On the other hand, if the tendency to disintegration and suppuration prove the stronger, large sacculated cavities are formed, communicating with each other by fistulous tracts, some of which may open externally, pus being discharged from them which contains the little masses (fungus cores) already mentioned, which consist of the fungi in clumps. The walls of these sacs are for the most part lined with granulations containing colonies of the fungus.

In the case of cattle, the disease most frequently attacks the lower jaw, then the upper jaw, tongue, pharynx, larynx, œsophagus, stomach, and intestinal wall. It may also invade the skin, lungs, subcutaneous and intermuscular connective tissue. In cases observed in the human animal the disease has generally attacked the soft parts of the neck, the thorax near the spine, the mediastinal tissue, and the lungs. In one case the infective material gained access to the blood-current and gave rise to metastatic foci.

These inflammatory growths seldom reach any great size in man, being apt rather to break down early; but in cattle the tumors, especially when located upon the jaw-bone, may attain considerable dimensions, being frequently as large as the top of a hat.

When this process invades bone it leads to destructive caries. This is notably the case with regard to the vertebræ in man, or the jaw-bones in cattle. In fact, in all affected regions the destruction of tissue is considerable.

As regards the genesis of this disease, it seems very probable that the mouth is usually the starting-point of the infection. The specific fungus has been found in the crypts around the tonsils, hollow teeth, and similar situations in the buccal cavity of healthy individuals. The infection probably then follows wounds of the mouth, the extraction of teeth, or any injury that gives the spores of the fungus a chance to enter the living tissues, where it finds a suitable habitat for its development.

Thus, in cattle, if an animal has a scratch or cut on the tongue, and the fungus spores gain access to it, the result may be actinomycosis of the tongue, or as the farmers in England call it, "wooden tongue." Actinomycosis of the jaw in cattle occurs not infrequently, and here the spores of the fungus are supposed to gain access to the interior of the bone through the alveolus of a tooth, when a temporary is shed to make room for a permanent molar.

When actinomycosis occurs in the lung it is believed to be due, as a rule, to inhaling the spores with the inspired air.

Metastasis is not common, although it may occur. As a rule the disease is marked, clinically speaking, by its chronic course and local malignancy.

Treatment of cattle suffering from actinomycosis may avail in some forms of the disease. For example, in

cases of "wooden tongue," when the nodule first appears, it may be cut out and the wound painted with tincture of iodine, with a fair prospect of satisfactory results. The iodide of potash treatment is also said to be of considerable value, and experiments with it have recently been tried by the U. S. Bureau of Animal Industry in order to ascertain its efficacy in treating bovine actinomycosis, and the results in many cases have been very successful.

In cases where the jaw is attacked, the best course is to fatten the animal as rapidly as possible for beef, as the disease is usually local, and when this is the fact it is not likely that the flesh is dangerous as an article of food. This view is borne out by the fact that bovine actinomycosis is by no means a rare occurrence in this country, while in the human being it is found to be very infrequent—so much so that it is almost never met with. The animal suffering from this trouble should be fattened as early as possible, as when the tumor attains a large size it interferes with eating; finally it breaks in places and continually discharges, the creature losing flesh and wasting away.

In actinomycosis of the jaw a swelling appears, small at first, growing slowly and continually, until it becomes of considerable size; it may in time ulcerate in spots, and these ulcers will be found to be the openings of fistulæ leading into the bone substance, from which there is a constant discharge of thin purulent material, containing little flocculi, these being clumps of the fungus. The tumor is hard and painful, and when the sores appear upon it, disgusting to the sight. This disease cannot be particularly infectious, as one or two animals in a herd may have it and yet the others remain perfectly healthy; although it is usually fatal to men or animals unfortunate enough to contract it.

The actinomyces germs are probably taken into the system through the mouth, being contained in the food, as the parasite has been found in chaff and husks of grain, in siftings from grain, in corn-stalks, and the like. As it has been found also frequently between the teeth, in hollow teeth, and in nooks and crannies in the mouths of healthy animals and men, it would seem that the fungus cannot obtain a foothold where the mucous membrane is healthy, but only where some abrasion of it exists.

Actinomycosis seems to occur frequently in the tongue among cattle in the low-lying fen districts of England; while in the United States it is met with chiefly in the West, and here the jaw, usually the lower one, is the point most commonly invaded.

That it is possible for actinomycosis to be transmitted from animals to man is proved by the following case: An Austrian veterinary surgeon upon the Russian frontier, who was employed to examine cattle by the Austrian government, was in the habit of holding bits of paper connected with his work in his mouth while he examined the animals, some of which had actinomycosis. In some way, by handling first the cattle and then the papers, he became infected with the disease, the tongue being the organ involved. He recognized the trouble early, however, had the nodule removed and the wound suitably dressed, and he made a complete recovery.

Another instance of its infectiousness is illustrated by the following case: A horse having a wound on the stifle, was placed in an empty shed, which had formerly been occupied by some cattle, with the result that actinomyces gained access to and developed in the injury.

TUBERCULOSIS.—Tuberculosis among the domesticated animals is seen very much more frequently among bovines than any other species, and occurs in the milch-cow in more instances than in any others of the family. It is in this country, from a sanitary point of view, of more importance than any other malady communicable from the lower animals to man, because so little has been attempted toward preventing its ravages by legislation. Tuberculosis in cattle is probably as dangerous to the human family as glanders among equines would be if no laws had ever been enacted providing for the slaughter of glandered horses; and it is more dangerous than the occasional outbreaks of rabies among dogs that occur from time to time in various localities; yet the danger to the human race from this source has never been fully realized, as the disease is so insidious in its attack, and so gradual in its development, that it is seldom that the relation between cause and effect is traced out here, as it is in a case of glanders in a man known to have had the care of a diseased horse, or of rabies in a person known to have been bitten by a mad dog.

Bovine tuberculosis is an important affection from two points of view: first, from that of the sanitarian, who wishes to prevent, as far as possible, the ravages of a most destructive malady among the human race; secondly, from that of the farmer, who desires to keep from his herd a troublesome and dangerous infectious disease. Hence, in some of the few States where legislation for its suppression among cattle has been attempted, the work has been placed in charge of the State Board of Health, while in others it has been turned over to the State Board of Agriculture, or to a special cattle commission.

A tubercle is simply a nodule, and the name tuberculosis conveys to the mind at once the idea of a disease whose characteristic feature is the formation of nodular growths in various organs of the body. Of course, it does not follow that every nodular growth found in the organism implies tuberculosis, as there are other diseases in which nodules are found; for example, in glanders nodules may be present in the lungs or possibly in other organs, which are spoken of as the nodules, or tubercles, of glanders. Therefore two adjectives are used in connection with nodular diseases: the term *tuberculous* is applied to the lesions of *tuberculosis*, and *tubercular* is used in speaking of nodules that resemble tubercles when the malady *is not tuberculosis*. In all the infective granulomata there are *tubercular* appearances, but these are only *tuberculous* when the disease is *tuberculosis*. There may be in some other disorders tubercular appearances, to the naked eye at all events, which are due to some other cause.

Virchow describes a tubercle, when newly formed, as a small gray, translucent nodule, not exceeding a millet seed in size, mainly composed of cells, and developed from connective tissue. The cellular elements are essentially similar to those of lymphatic glands; they are round cells of various sizes, some of them like white blood-cells, some larger, and some smaller. These cells contain nuclei, single in some cases, in others there may be two or a number, these poly-nucleated cells being the giant cells. Some of the cells may become flattened, giving them an epithelioid appearance. Between the cells are found fibrous filaments arranged in a network, and sometimes vessels also. The latter are never new-formed, but existed before the tubercle was developed, and lie within it simply because it has grown around them. These nodules may occur singly or in numbers; or they may be grouped in confluent masses. In the latter case the internodular tissue does not remain unchanged, but seems to be made up of imperfect granulation-tissue, giving it the appearance of a compact, uniformly diseased mass, rather than normal tissue containing nodular deposits. As a nodule becomes older the centre becomes soft and cheesy. It is then yellowish-white and opaque, under the microscope it appears as a granular friable mass at the centre, while the outer portions retain the cellular constitution; these cells also appearing to spread out into the normal surrounding tissue. This caseation of the centre of the nodule is due to the growth increasing to such an extent as to press on the blood-vessels, shutting off the supply of food to the central portion, causing the cells to die and break down; thus the centre of the tubercle becomes softened and cheesy. A number of tubercles may become confluent, and then as the centre of the mass breaks down it leads to the formation of a large cheesy body, and this may be spoken of as a tuberculous abscess. Very rarely the tuberculous nodules may become fibrous instead of cheesy. In later stages still, lime salts may become deposited in the cheesy mass; then it becomes hard and a knife drawn through it grits, as it would if drawn through particles of coarse sand in

the substance of the nodule. In cattle tubercles are rarely found in large numbers of a miliary type; the tendency is to form large nodules, or masses, and also to become infiltrated with lime salts, and in cattle kept under good hygienic conditions there is also a tendency for the disease to develop slowly, taking on a more or less chronic type, the animal often living for years in a diseased condition.

In cattle there is also a tendency to form bunches of grape-like masses upon the serous membranes of the thoracic and abdominal cavities; these pearly nodules are the "Perl-sucht" of the Germans, and among English butchers are known as "grapes."

Tuberculosis was formerly separated into several diseases, which were described as different affections, but modern discoveries have shown that some of the maladies which were described separately are in reality tuberculous. For example, scrofula, lupus, and the like are now all known to be tuberculous. Cattle may have tuberculosis in about all the forms known in man, such as *phthisis pulmonalis, tabes mesenterica,* tuberculous arthritis, tuberculous meningitis, scrofula, lupus, etc. It may be general or local, but as a rule is met with most frequently in the lungs among bovines and least frequently (almost never) as lupus. Tuberculous arthritis, and tuberculous meningitis, while not common, are occasionally met with. The identity of tuberculosis in man and animals was long questioned, and among the medical profession its infectiousness was not generally believed in, until Koch's work on the etiology of the disease settled the matter for all time; and at this place a consideration of the etiology of tuberculosis is appropriate.

Etiology of Tuberculosis.— Until within a few years but little or nothing was known of the cause of tuberculosis; all kinds of vague ideas were held as to its origin, but most of them were very wide of the mark. Within twenty-five years it was shown, by some continental veterinarians, that the disease could be artificially induced by feeding tuberculous material from infected organs, and milk from tuberculous cows, to calves, pigs, and other small animals, and that it could be produced in rabbits and guinea-pigs by inoculating them with tuberculous products.

Several years before the real cause of this disease was known, Professor Walley, an English veterinarian, speaking of it, said: "In whatever way I consider tubercle as tubercle, my mind always reverts to the same conclusion, viz., that tubercle is as much a specific disease, whether inherited or acquired, as glanders, syphilis, or any other affection of the kind with which we are acquainted."

Many veterinarians for a number of years have known tuberculosis to be infectious among cattle; but the idea that it was an infectious disease was not generally accepted by the medical profession until within the last eleven years, for various reasons, one of which was that all observers did not acknowledge the identity of tuberculosis in man and animals.

Finally, all disputes as to the etiology of tuberculosis, and the question as to whether the disease was identical in the human and lower animals, was settled by the great discovery of Dr. Robert Koch, of the Imperial Board of Health, in Germany. At a meeting of the Berlin Physiological Society, held on March 24, 1882, Dr. Koch communicated some of the results of his researches on tuberculosis, which constituted a distinct advance in the knowledge of its cause. He announced that the tuberculous virus is a special germ, the *bacillus* of *tuberculosis.* Its length is about the third of the diameter of a red blood-cell, and its length is about five or six times its breadth as a rule, although it may be a little more or less. Individual bacilli may contain bright clear spores, or vacuoles. The bacilli are found chiefly in new tubercles, more sparingly in older ones; some of them lie within the cells, and especially within the giant cells, others lie outside. They are generally single and scattered, or may be found in groups and clusters. Koch discovered the bacillus without staining it, and must have had a wonderfully sharp and well-trained eye to do so, as an ordinary observer would not be able to see it unstained even if he knew it were in the field of the microscope. Other German scientists have experimented with staining it in various ways, until now there is a certain definitive way of staining the bacillus of tuberculosis, so that it cannot be confounded with any other; the only other bacillus having the same staining reaction is the lepra bacillus, which is shorter and only found in leprosy.

Koch has shown that the tubercle bacillus can be cultivated upon sterilized blood-serum (it can also be grown upon glycerine agar); it grows only in a constant temperature apparatus not below 30° C. or over 41° C.; it is therefore very doubtful if it can multiply naturally outside of the animal body. He also demonstrated that bacilli thus bred may then be introduced into the bodies of various animals, such as rabbits, rats, dogs, and guinea-pigs, and tuberculosis is thereupon induced; that is, they are attacked by a disease characterized by a progressive formation of cellular nodules. These nodules always contain the characteristic bacilli. In guinea-pigs the first appearance of the disease is manifested ten days after inoculation.

Tuberculosis is the same disease in both man and the lower animals, as the specific bacilli are found in the nodules of all, having the same general shape and size, and peculiar staining reaction. Scrofula and lupus, formerly not considered to be identical with tuberculosis, are now known to be, as the characteristic bacillus is always present in these affections, as it is in what has always been called tuberculosis. In considering the causes of a disease they may be divided into two classes, the exciting cause, and the predisposing causes.

The exciting cause of tuberculosis is the specific bacillus which occasions the disease. Clinical experience would seem to indicate that the tubercle bacillus is no ordinary bacterium, such as may enter and affect any organism without distinction; it would seem rather as if infection occurred only where a definite predisposition exists, or where a considerable quantity of virus is introduced, in some cases constantly or at frequently recurring intervals. This predisposition may be local or general. A local predisposition may depend mainly on some antecedent inflammatory change, for example a cold followed by consumption. A general predisposition is attributed especially to scrofulous subjects; this tendency to become scrofulous or tuberculous used to be spoken of as a *scrofulous* or *cachectic diathesis.* These terms were applied to persons whose tissues exhibit a certain frailty or susceptibility to injury, that makes them particularly liable to chronic inflammatory disorders. Often the term "scrofulous" is applied to persons or animals actually suffering with tuberculosis, as well as to those which are only predisposed to it.

Beside the bacillus as the exciting cause of tuberculosis, there are certain predisposing causes to be taken into consideration. The following list is similar to one found in Walley's "Four Bovine Scourges," but is modified a trifle in order to have it in accordance with the latest knowledge on the subject.

Predisposing Causes of Tuberculosis.—1, Species of animal; 2, hereditary predisposition; 3, congenital; 4, breeding in and in; 5, breed; 6, early, late, and overbreeding; 7, physical conformation; 8, climate and locality; 9, debility produced by lactation, sickness, and bad food; 10, bad hygienic conditions.

1. *Species of Animal.*—The bovine tribe is pre-eminently disposed, equally so with man, to acquire tuberculosis. The rabbit is very subject to it, and in some rabbit warrens in England these little animals have been almost annihilated by this disease. Guinea-pigs also develop it very easily when used for inoculation experiments. Of the farm animals the pig is the most susceptible next to the cow, but as this animal is generally killed at an early age the tubercles generally escape observation, as these animals are usually so slightly diseased that their general health is not impaired. Tubercle is rarely seen in the sheep, cat, or dog, and more rarely in the goat. It is so rare in the horse as to be almost unknown in this species, although there are a very few cases

of the malady on record in the equine. It not infrequently occurs in fowls, and it is said that it may also attack game birds. In zoölogical gardens in climates similar to the United States, Northern Europe, or England, it often causes great havoc among animals from tropical countries; it is here very common among monkeys, antelope, and deer, and has also been observed in birds and snakes, as well as occasionally in the carnivora; it would therefore seem to be common to many animals beside man.

2. *Hereditary Predisposition.*—Persons or animals born of a parent or parents affected with tuberculosis, have what is known as an hereditary predisposition to the disease. That is, they have a tendency to acquire tuberculosis much more readily and easily than the offspring of strong, rugged parents free from this malady; if exposed to infection their tissues have not the same power of resisting the virus. Animals with this predisposition (including the human animal) were formerly said to have a "scrofulous," or "cachectic diathesis."

3. *Congenital.*—Congenital tuberculosis is very rare, all the weight of evidence going to show that it almost never occurs. Professor Johne, of Dresden, records a case in a newly born calf. Other veterinarians have recorded cases, but in some instances the young animals were not killed until they were several weeks old, and then they were but slightly diseased, so that it is possible that in some of the so-called congenital cases the disease was acquired after birth. As a rule, it seems to be the will of a great and wise Creator that the offspring of tuberculous parents shall at least have an opportunity to start in life free from this scourge, and that in almost every instance it is acquired after birth.

4. *Breeding In and In.*—This may be classed as another potent predisposing cause, when carried to extremes, as it tends to weaken the constitution of the progeny.

5. *Breed.*—Breed plays an important part in the production of tuberculosis among cattle. Those most subject to it are the Jerseys and Guernseys; certain strains of the Ayrshire are prone to it, while other families appear to be very hardy. Herefords are said to be not particularly predisposed; it is not common among Devons, but does occasionally occur among them. Some families of Shorthorns are very subject to tubercle, while other strains of the same breed are remarkably free from it; in this breed hereditary predisposition plays an important part. Holsteins are, as a rule, hardy cattle, but are by no means exempt. In short no bovine is exempt from this disease, although some resist infection much more than others. The hardy New England stock, "natives," as they are called, are less liable to tubercle than pure breds, and those breeds coming from warm, even climates are in the changeable, rigorous climate of the Northern United States and Canada, with its great extremes of temperature, more subject to tubercle than breeds originating and kept for several generations in a climate resembling it.

6. *Early, Late, and Over-breeding.*—Cows which are bred from at a very advanced age, heifers which calve when very far short of maturity, and cows bred from year after year, giving at the same time, perhaps, large quantities of milk, or butter-forming material, have their systems so depleted that their young have not the strength and vitality that they would under more favorable conditions, and consequently these calves have a greater susceptibility to tuberculosis than they otherwise would. These same depleting influences also cause the mothers to be in a condition more favorable to the development of this disease.

7. *Physical Conformation.*—In man and cattle physical conformation plays an important part in the tendency to acquire tuberculosis. Cattle with narrow chests, light barrels, and disproportionately long legs, are undoubtedly predisposed, but at the same time it must be borne in mind that these peculiarities in themselves are often evidences of a tuberculous diathesis.

8. *Climate and Locality.*—Although this disease is found over the entire globe, yet it is more destructive in some localities than in others. In Mexico it is said to be very prevalent, thirty-four per cent. of the cattle killed for food there are said to have it. (*Vide* Fleming's "Sanitary Science and Police," Vol. ii., page 368.)

A moist, changeable climate is more favorable to its development in animals and man than where the air is dry and rare and the temperature less variable. Cattle in the dairies in the neighborhood of large towns and cities are to a much greater extent the victims of tuberculosis than those in a distinctly farming community. In the vicinity of large cities infection from diseased to healthy cows plays an important part in its spread, there being a constant buying and selling among milkmen; and once it obtains a strong foothold in a herd it may take some time to eradicate it.

In the dairies surrounding large cities, bad hygienic surroundings also play an important part in its development.

9. *Debility from Various Causes.*—One of the most fertile causes of a low tone of the system among cows is the depleting influences of lactation; animals giving immense quantities of milk are much more liable to tuberculosis than other cattle, because it is a constant strain upon the general health of the creature. The cow in a state of nature gives only enough milk for her calf, and in a few months becomes dry again as soon as her young can shift for itself; but man has converted her into a mere milking machine, giving enormous quantities of milk for the greater part of the year, and this is necessarily a great tax on the constitution, rendering her much more susceptible to diseases of various kinds.

Sickness of any description is another predisposing cause, as an animal recovering from an exhausting illness, if exposed to the infection of tuberculosis, is much more likely to contract it than if in a condition of perfect health.

Another predisposing cause of tuberculosis among cattle is bad food; an animal fed upon an inferior, indigestible quality of food, perhaps deficient in quantity as well, has the system reduced, and is in a condition of greater receptivity than one fed upon a sufficiency of nutritious, healthful material. Bad food might be classed under "bad hygienic conditions" as well as under "debilitating influences."

10. *Bad Hygienic Conditions are also Predisposing Influences to Tuberculosis.*—Animals housed in hot stables, kept hot by the heat of their own bodies, and with no change of the atmosphere, for fear of allowing cold air to enter, are much more susceptible to this disease than where there is an abundant supply of fresh air; it also gains headway more rapidly in a dark stable. Cattle should be maintained in light, well-ventilated, high-studded stables, and if they are to be warmed in winter the heat must come from some other source than the warmth of the animal body. A stable with a large cubic air-space is not sufficient, but there must be a constant substitution of fresh for contaminated air.

The Dissemination and Propagation of Tuberculosis.—Tuberculosis is ordinarily acquired in three ways: 1, By inhalation; 2, by ingestion; 3, by inoculation.

Tuberculosis acquired by inhalation is the form seen in the great majority of cases both in man and cattle, the tubercle bacilli gaining entrance to the lungs in the inspired air. Under these circumstances the lungs are probably primarily affected, and the disease spreads from here to other organs. Here the first symptom is the cough, and a man or other animal suffering from phthisis is constantly coughing up and expectorating (at least, the man expectorates; animals simply cough out) morbid products from the lungs; this sputum contains numbers of tubercle bacilli, and when it dries and becomes part of the dust floating in the atmosphere, the bacilli also float with the dust and may gain access to the lungs of healthy animals. Now, if a person or animal is just recovering from a severe cold and has a little ulcerated spot in one lung, the bacilli may gain a foothold there and grow and produce the disease, spreading from the original point to other parts of the lungs and to other organs. Or, if large numbers are present in the air of a

room, a person constantly inhaling them may become infected, even though naturally quite healthy, being finally overcome by numbers. The bacilli of tubercle retain their vitality for a long time; Koch has found that after several months in a dry room they still were capable of producing the disease. Dr. A. K. Stone, of Boston, Mass., has demonstrated that dried tubercle bacilli retain some of their virulence for at least three years (*American Journal of the Medical Sciences*, March, 1891).

Nearly everyone has doubtless inhaled these bacilli; but when present in small numbers, and with the pulmonary mucous membrane healthy, the ciliated epithelium of the air-passages returns them to the throat, and they are expectorated. Then the colony is so slow in growing at first that it may have a difficult time in fixing itself permanently.

Phthisical patients in expectorating are constantly giving out germs which may infect other people, and possibly cattle; and *vice versâ*, there is a possibility that a person of a cachectic diathesis working in a stable occupied by tuberculous cows may acquire phthisis from them.

Infection by ingestion means acquiring the disease through the digestive tract by swallowing the virus, and this method of infection is of special interest in a consideration of the malady from a veterinary sanitary standpoint, as it is from the use of the flesh and milk of tuberculous animals that the chief danger lies of infection by this method. Tuberculosis by ingestion may also result from secondary infection, a tuberculous patient swallowing his own sputum. Tuberculosis by ingestion may also be caused in pet dogs with morbid appetites, or in fowls, by swallowing the sputum of a consumptive person.

The use of milk or dairy products from cows suffering from tuberculosis is probably very dangerous—at least it is if the effect upon children is equal to the effect it has upon calves and pigs.

The writer feels as though he could speak authoritatively upon this subject, as he was employed by the Massachusetts Society for Promoting Agriculture, in conjunction with Dr. H. C. Ernst, of the Harvard Medical School, for three years, from January, 1888, to January, 1891, in the study of tuberculosis, with special reference to the infectiousness of the milk from cows suffering with this malady. The Society leased a farm near Boston, as an experiment farm, and here and at the bacteriological laboratory of the medical school the investigation was conducted. At that time but little was known concerning the presence of the tubercle bacillus in milk, but it was thought that a cow must be suffering from a diseased condition of the udder in order to give these bacilli in the lacteal fluid, and also that it was to be found only in the sediment after allowing the milk to settle. It was found that a cow suffering from general tuberculosis can give the bacilli in the milk, even although the udder is healthy, and also that they are quite as likely to occur in the cream as in the sediment. Recent continental observations go to show that the tubercle bacilli from diseased cows may also be present in the butter and cheese made from their milk; this is not surprising, as there is no reason to suppose that the process of cheese or butter making should remove this germ.

In the investigations conducted under the auspices of the Massachusetts Society for Promoting Agriculture, out of samples of milk examined from 36 cows, 10 gave tubercle bacilli in their milk, or about twenty-eight per cent. Of the ten giving the bacilli in the lacteal secretion, three or four had tuberculous mammitis, but the majority were cases of general tuberculosis with healthy udders. Of the 36 cows, about twenty-five belonged to the Society at one time or another; the others were animals that it was unable to obtain possession of.

Calves and pigs were fed upon the milk of these cows for periods of about six months each; at the end of that time the young animals were killed, and careful post-mortem examinations made; every abnormal part of an organ was saved for microscopic examination, and nothing was called tuberculous unless the specific germ was found in the specimens examined. Each calf was fed the milk from a certain cow (except in a few instances where the milk of two cows nearly dry was mixed, in order that the calf should have enough food), and had its own particular pail which was scalded out every day. The calves were kept in a separate building from the cows, each calf in its own pen; so the only way in which it could become infected was through the medium of the milk brought to it.

The pigs were not the subjects of special experiment, but were simply given the surplus milk from the various cows. Every calf dropped by a diseased cow on the place was killed when but a few days old, and the calves bought for feeding experiments were always carefully selected as the offspring of healthy mothers, as far as it could be ascertained.

Twenty-five calves and twelve pigs were used in these feeding tests, and when they were killed the post-mortem examination showed that about forty per cent. of each were tuberculous. Most of them were at the time of slaughter in good health to all external appearances, and the autopsy revealed very few morbid changes, perhaps two or three little nodules no larger than a very big grape-seed in the liver; in one calf only a slight alteration in the appearance of one kidney was noted, but under the microscope these nodules possessed the usual appearance of tubercles, and the characteristic bacillus was found, showing that the disease was present, and only awaited a favorable opportunity to develop itself still farther. In the case of heifers the depleting influence of lactation often causes the disease to develop rapidly.

Rabbits and guinea-pigs inoculated with milk or cream containing the bacilli of tuberculosis, by means of subcutaneous injections of it upon the abdomen, develop the disease and die of it in a few weeks, unless killed for purposes of autopsy before allowing them to die of themselves. In a few instances these little animals developed tuberculosis, after being inoculated, when no bacilli were found by microscopic examination of the milk; this shows that the bacilli were present in small numbers, but none were in the slides examined. This is not surprising, considering that only a few drops from a sample of milk or cream can be examined, and the extent to which these germs are diluted by the fluid containing them; the only wonder is that they were found as many times as they were.

In fact, in an examination of milk for tubercle bacilli the easiest and surest test is by inoculation experiments upon these little animals, rather than by microscopic examination, which entails a great deal of work and the expenditure of much valuable time.

Samples of milk were examined from the first and last parts of the milking, with the result that the bacilli could very well occur in either; it was also found as frequently in the cream as in the sediment, and it was ascertained that a cow giving them in the milk does so with a considerable degree of constancy.

These results are borne out by the researches of Bollinger, Bang, and other continental scientists, as well as by Dr. Leonard Pearson, of the Veterinary Department of the University of Pennsylvania.

The danger from the use of the flesh of tuberculous animals killed for food has been less studied than the question of milk, but it is pretty certain that the meat of these creatures is unfit for human consumption unless thoroughly cooked. The danger from the use of the meat of these animals is, however, very much less than from milk and dairy products, as it is generally customary to eat thelatter uncooked, while the former is usually subjected to enough heat to kill the germs.

In abattoirs in Europe, and also at the Brighton abattoir, near Boston, veterinary inspectors are appointed whose duty it is to condemn all carcasses which are affected with tuberculosis to any great extent, although if the disease is localized in a part of one organ the meat is not then considered dangerous.

Dairy inspection is but a matter of time, and is sure to come. In Massachusetts the law requires that all milk sold must contain thirteen per cent. of total solids, yet

no regard is paid to the health or sanitary surroundings of the cows.

During the past year the New York State Board of Health has made a good beginning in this direction, examining dairy herds and killing all tuberculous cows found, and destroying the carcasses. The only way in which milk can be rendered safe when nothing is known of the source from whence it comes, is to sterilize it by steam heat; this should always be done with infants' milk in summer, as it destroys various injurious germs which may cause cholera infantum and similar disorders.

Infection by Inoculation.—Infection may occur also from inoculation when the virus enters the body through the skin, and may be either accidental or intentional. It is intentional when tried experimentally upon animals, and accidental if the virus enters the system through a scratch or cut on the skin. Accidental inoculation might occur to a person who cut or scratched his hand while making an autopsy upon a tuberculous animal, or while performing an operation upon a tuberculous subject. When the disease is induced by inoculation it begins with a nodule at the point of entrance, but if it is the result of ingestion the bacilli may enter the circulation and first attack some organ that has a lesser resisting power than other organs.

Tubercle bacilli may be excreted in small numbers in urine or fæces, but this is a less fertile source of infection than sputum or contaminated food.

The transmission from man to man, or from bovine to bovine, is chiefly due to the inhalation of dust from the desiccated sputum, but at the same time it must not be forgotten that tuberculous food products are dangerous, and have probably caused many cases of consumption that have never been laid to their door.

Diagnosis of Bovine Tuberculosis.—This disease is so insidious in its attack, and so gradual in its development, that in its early stages it is very difficult of diagnosis; but as it progresses, in time almost anyone can tell what the trouble with the animal is, if he has any knowledge of cattle at all. In advanced stages of the disease the emaciation of the patient, the great weakness and lassitude, the frequent distressing cough, the quickened respiration, and appearance of general unthriftness, tells the merest novice at a glance the nature of the disorder.

But this is only after the trouble has existed for some time; a cow may be tuberculous for years if she is under good hygienic conditions, the malady frequently having a tendency to assume a chronic character in cattle; she will give a fair quantity of milk, and her general appearance will be thrifty to an inexperienced eye, or for that matter, perhaps to even an experienced one; she will calve regularly, and perhaps in the course of time die of some other sickness, or be killed for beef because her days of usefulness are ended at the milk pail; when the butcher, to his surprise, may have to throw away her carcass, if he be a conscientious one, or, as is more frequently the case, her flesh will be sold for food, a fitting climax to her death-dealing career.

As an example of this the cows kept at the experiment farm, by the Massachusetts Society for Promoting Agriculture, will serve. Some of them were kept for two years, remaining in much the same condition during that time as when first purchased, and in a few instances even improving in health; in fact, there were two that may be said to have actually recovered by simply being placed under the best of hygienic conditions, and not forced by feeding to a large yield of milk.

It is an exceedingly difficult thing, then, to diagnose a case of tuberculosis in a cow, when it is in its incipiency or when it assumes a chronic form, advancing in its development very slowly. In dealing with tuberculosis in a lot of cattle, if no well-marked cases are present, it is often of great value to know the previous history of the herd; if one is told that animals have previously been killed in it for this affection, he is naturally led to consider certain creatures suspicious that he might not suspect if he knew the herd had always been healthy. It is not necessary that a cow should have *phthisis pulmonalis* in order to be tuberculous, for she may have tuberculous arthritis, scrofula, *tabes mesenterica*, or tuberculosis of other organs, and at the same time the lungs may be free, or comparatively free, from the disease. In examining a cow, then, besides examining the lungs and noticing whether there is a persistent cough, notice also whether the external lymphatic glands are enlarged and hard; observe whether she is free from lameness; find out if she is at times constipated and at others affected with diarrhœa (as they are in *tabes*); learn, if possible, whether she is a nymphomaniac (commonly called by farmers a "buller"); ascertain if abortion is a frequent occurrence in the herd, although this is of little value, as there is an infectious form of bovine abortion that has nothing to do with tuberculosis; and examine the udder and see if it is nodulated, or what is commonly called "gargety." Any or all of these symptoms may aid in making a correct diagnosis, especially if it is possible to obtain a reliable history of the previous health of the herd, which it is not always an easy thing to do.

In making a physical examination of the lungs of a bovine, percussion is not of much value, owing to the thickness of the hide and of the thoracic walls, and to the large area covered by the scapula. Auscultation is of a good deal of value, and in order to become expert at it the best way to do is to auscultate the lungs of a large number of healthy cattle, until a thorough knowledge of the normal lung sounds is obtained, when it will become much easier to discern any departure from these in examining a diseased animal. If a large area back of the shoulder is solid, there will be a loss of respiratory murmur; if the area is superficial, a tubular sound may be heard; and if there are small diffuse tubercles through the lungs, there may be a partial obstruction to the lumen of some of the bronchi causing piping sounds. If there are tuberculous deposits upon the pleura, pleuritic friction sounds may be heard.

There are other diseases of cattle that may produce lung sounds similar to tuberculosis, and which are often difficult to differentiate; for example, in bronchitis or broncho-pneumonia there may be mucus in the bronchi that will produce piping sounds very difficult to tell from the piping heard in some cases of tuberculosis. Patches of pneumonia may cause loss of respiratory murmur and dulness on percussion. Parasitic bronchitis, caused in young cattle by the *strongylus micrurus*, is a cause of a frequent distressing cough and much bronchial irritation that might deceive the inexperienced. Ordinary pleurisy may cause friction sounds, that may become permanent if adhesions are formed; and pulmonary emphysema, common in old cattle, may lead to exaggerated respiratory murmurs.

The clinical thermometer, as an aid to diagnosis, is of so little value that it is simply a waste of time to take a cow's temperature in an examination for tuberculosis; there is rarely any fever, unless some degree of sepsis be present from an abscess in the lung containing all sorts of bacteria, besides the tubercle bacillus. The normal temperature of the cow ranges from 101° to 102° F., and in advanced pregnancy may be nearly 103° F., and in old depleted subjects may not be more than 100° F. The temperature of animals is taken per rectum, or occasionally per vaginam.

The microscope will occasionally be found of great value in the hands of the scientist in diagnosing bovine tuberculosis, by cutting out enlarged glands and examining them; or the examination of milk or various secretions revealing the presence of the specific germ, the *bacillus tuberculosis*, will settle the question beyond all doubt.

A possible, but not always convenient, way of diagnosing pulmonary tuberculosis in the ox tribe, is to cut a slit in the trachea and pass down it, as far as possible into the lung, a long wire with a bit of sterilized sponge or sterilized absorbent cotton on the end, withdrawing it, and smearing any pulmonary secretion upon it on a cover glass, dry, and stain; if any tubercle bacilli are found it is a sure confirmation of the diagnosis in a suspicious case.

Occasionally a scrofulous cow may have a tuberculous

gland back of the pharynx, or in closer proximity to the larynx, which will cause more or less obstruction to the entrance of air to the trachea, resulting in her emitting a roaring sound when breathing; this sound may be constant, or there may be intervals of relief, but no hesitation need be felt in making a diagnosis in such cases, as any other cause of the difficulty is so rare that it is safer to lay aside the possibility of its being something else than to run the chances of letting a tuberculous animal escape.

Another method of diagnosis that has not been sufficiently investigated to warrant its being taken up in field work as yet, but which is spoken of highly where it has been tried as a matter of experiment, is subcutaneous injections of Koch's tuberculin. It is said that if a cow suffering from any form of tuberculosis, no matter how slight, receive a subcutaneous injection of Koch's tuberculin of from 0.2 to 0.3 c.c., depending upon her size and age, in the scapula region or side of the neck, there will be a marked reaction of a febrile character following in the course of ten or twelve hours, the temperature rising in from twelve to fifteen hours as high as 106° F. to 107° F., then gradually falling very slowly until it reaches the normal again, in from twelve to twenty-four hours more. When this method is pursued the animals are inoculated in the evening after milking, and the temperatures are then taken at the time, and every three hours thereafter for the next twenty-four hours. Every tuberculous creature, no matter how slightly diseased, should react, and it is very seldom that any but an affected animal reacts; but it is said that in rare cases a cow with a maximum of disease, inoculated with a minimum of the tuberculin, will not react; but, as has already been said, this method of diagnosis needs to be further experimented with before it can be said positively to be adapted to the sanitary inspection of herds. If it proves a success it will furnish a simple and ready means for the diagnosis of tuberculosis, with a view to its eradication among cattle, although even then it can be urged that many animals would react to it that had not become either a danger to other cattle or to the public health.

Post-mortem Appearances of Cattle Suffering with Tuberculosis.—The post-mortem appearances found in a cow that has died with, or been killed on account of, tuberculosis, depend upon the organ or organs diseased. Tuberculosis may be localized in a single organ, or it may be general and affect nearly all of the thoracic and abdominal viscera.

The general appearance of tubercle in the different organs is much the same, as already described; when they occur in the lungs they may at first be miliary, but they grow and form whitish nodules the size of a pea or larger, and as they grow they may become confluent, forming masses, and finally invade so much of the lung tissue that that viscus, instead of weighing three or four pounds as it normally would, may weigh from fifteen to twenty. As the centre of a tubercle becomes deprived of its blood-supply by the growth of its periphery, it becomes broken down and "cheesy;" later, if lime salts are deposited there, it becomes calcareous. A number of tubercles in the lung coalescing and becoming cheesy, may form a large abscess, possibly capable of holding several quarts; this abscess may break into a bronchus, and its contents be discharged through the mouth, leaving a vomica. The formation of tubercles does not vary much throughout the body; there is the nodule of variable size composed of granulation tissue, if looked at under the microscope, the outer cells flattened by pressure resembling epithelium, and also containing the giant cell; besides this the tubercle bacillus *must* be present to complete the diagnosis.

In the thoracic cavity, beside the lungs, tubercles may develop upon the pleura, especially the parietal layer, at its inferior part particularly, forming large masses resembling clusters of grapes, the "*Perl-sucht*" of the Germans, and "grapes" of the English butchers. These may be in various stages of development, from a newly formed one to a cheesy or calcareous nodule. Adhesions may be formed between these clusters and the lungs, cementing the latter firmly to the ribs. Tubercles in the thoracic cavity may also exist in the lymphatic glands in the space between the lungs, also in the outer layer of the pericardium, and very rarely in the layer covering the heart. When a mediastinal lymphatic gland is tuberculous, it at first becomes increased in size; later, miliary tubercles may be seen in it; then the tubercles may become larger and cheesy, and later calcareous, or an abscess may form in it; these glands frequently become enormously enlarged, one normally the size of the end of the thumb often being as large as a full-sized cucumber. This description of a tuberculous lymphatic gland in the mediastinum will do for all, except that others rarely become so enlarged as in the mediastinum, with the exception of an occasional post-pharyngeal abscess. The enlarged lymphatics may be looked for in the submaxillary region, back of the pharynx, in the axilla, in the flanks, in the inguinal region, as well as in various parts of the thorax, abdomen, and rarely the intermuscular connective tissue. The bacilli of tuberculosis may sometimes be found in hypertrophied lymphatic glands before the formation of a miliary tubercle visible to the naked eye. If the bacilli can be found in an organ it decides a case as being tuberculosis. As a rule the bacilli are most plentiful, and consequently most easily found, where the tubercle is developing rapidly, that is, near its periphery, and as the centre becomes cheesy from the cells breaking down, the bacillus disappears, until it is very difficult, or else impossible, to find it.

Enlarged lymphatic glands in the region of the throat may cause difficulty in breathing or swallowing, and when in the thorax in close proximity to the heart, they may cause symptoms of heart disease.

In the abdominal cavity of the cow tuberculosis may attack any organ, but some more frequently than others; the liver is the one most commonly affected, but it may occur in the spleen, mesenteric lymphatics, the walls of the intestines, the ovary (causing barrenness and nymphomania—"bullers," they are called by the farmer)—occasionally the kidney, and not infrequently the peritoneum, may be studded over with nodules.

In the liver, spleen, or kidney the tubercles may appear as spots under the capsule of the organ, varying in size from a pinhead to a walnut; the larger ones may be undergoing destructive changes in their centres. Histologically, their structure is the same as already described.

In addition to the lesions already enumerated, cattle may have tuberculous meningitis, where tuberculous deposits occur in the vascular layer of the membranes of the brain or spinal cord, producing symptoms of delirium or paralysis, more or less complete, depending upon the extent and location of the deposit.

Last, and most dangerous of all, is tuberculous mammitis, or tuberculosis of the udder. In tuberculous mammitis it is very hard to differentiate between it and any other form of inflammation of the udder; the bag has an indurated feeling in one or more quarters, as though chronically inflamed from some cause, and it is impossible to tell it from any other form of irritation where the connective tissue in the gland is simply increased. After frequently seeing the cow and ascertaining that she is really tuberculous, it may then be inferred that the mammitis is tuberculous; or it may be discovered by a microscopic examination of the milk, or by an inoculation test upon guinea-pigs.

When tuberculosis of the udder exists the bag has a nodulated feeling upon palpation; these nodules may in time break down and discharge their contents through the milk-ducts.

On post-mortem examination in tuberculous mammitis there is found to be simply an increase of the connective tissue in the udder, but no tubercles, unless a few cells with bacilli are found upon examination with the microscope; but in tuberculosis of the udder nodules are present bearing the usual characteristics.

Cattle not infrequently have tuberculous arthritis, but lupus is a very rare, almost unknown, occurrence among them.

PROPHYLAXIS OF BOVINE TUBERCULOSIS.—The treatment of tuberculosis may do in man, but with animals it is neither practicable nor wise, and our efforts should be directed toward its prevention rather than its cure. The prevention of tuberculosis in man and animals is one of great sanitary and economic importance, which has only lately attracted the attention of health authorities since Koch's discovery awakened the world to the true nature of the disease. This is not the place to write upon the prevention of the transmission of tuberculosis from man to man, but the importance of averting its communication from animals to man, and from one bovine to another, cannot be too strongly insisted upon; the people should therefore be protected from the use of tuberculous meat and milk by a system of slaughter-house and dairy inspection. The flesh from animals badly diseased should be destroyed, and that from those slightly tuberculous should not be sold except with the understanding that it is to be thoroughly cooked. Milk from diseased cows should at least be sterilized, or better still, affected cows should be killed, both to protect the public health as well as to guard against their giving it to other cattle.

In regard to cattle, Walley, in his "Four Bovine Scourges," furnishes the following recommendations:

1. "All flesh and offal of affected animals, especially in advanced stages of the disease, should be destroyed by fire or otherwise."
2. "All suspected animals should be carefully isolated until pathognomonic signs have been developed."
3. "All actually affected animals should be slaughtered."
4. "All contaminated food, litter, etc., should be disinfected or burnt."
5. "All infected buildings should be disinfected."
6. "No animal whose history is tainted, even in the slightest degree, or in whose system there exists the slightest suspicion of tubercle, should be used for breeding purposes."
7. "Great care should be exercised at the period of birth to avoid any influences which will weaken the tissues in adultism."
8. "Breeding animals should be carefully shielded (as far as practicable) against debilitating influences of any kind."
9. "The system of feeding and general management of our high-class stocks should be regulated on a more rational and conservative basis than that on which it at present rests."

These rules, although written a number of years before the discovery of the tubercle bacillus, are in the main very good, and no exception can be taken to them. With the present knowledge of the matter it can be added, if the herd is healthy, keep the infection out by not allowing any tuberculous animals on the place. Neither should a consumptive attendant be employed, who might infect the cattle by constantly expectorating around the barn and upon their food.

If tuberculosis exists in a herd the diseased animals should be removed and destroyed, and their places disinfected before replacing them with new animals. Suspected animals should be removed from the herd and isolated in a separate building, until it can be decided whether they are or are not diseased.

Furthermore, the herd should be kept under the best hygienic conditions. Plenty of fresh air and sunlight, and not too warm a stable, will keep them in a condition in which they will be but little likely to contract the disease, and if an animal occasionally has it, if immediately removed from the herd and destroyed, there is little likelihood of others contracting the ailment.

The percentage of tuberculosis in cattle in the United States is very low. In an average dairy country it is not more than ½ to 1½ per cent., but in individual herds it may be very high, perhaps fifty per cent. of a herd of sixty or seventy cows being tuberculous; possibly this herd furnishing a milk route exclusively, the milk being sold perhaps in sealed glass jars at a price slightly above the usual rate, because it is "Jersey milk" from "Clover Dell Farm," or something of the kind. Hence the need of legislation of some kind as well as action by local health boards. In securing State legislation the disease has been looked upon from two standpoints, one as a matter of public health calling for action on the part of the State Board of Health, the other view being to look upon it as a matter of agricultural importance, considering the malady as one of the infectious animal diseases to be taken in hand by the State Board of Agriculture or by a State cattle commission. It makes little difference what board has the work in charge so long as it is well done.

The laws of two States are herewith appended as samples of legislation: that of New York, because it views the matter chiefly from the standpoint of public health, and that of Rhode Island on account of the preponderance which it gives to agricultural interests.

Any tuberculosis law should be worded in a way to allow for mistakes in diagnosis, as the best experts will make mistakes in diagnosing bovine tuberculosis; that is, it should provide for the slaughter of cattle having tuberculosis, or *suspected* of having tuberculosis, thus leaving a loop-hole in case a mistake is made; and also allowing animals to be killed when any doubt exists as to the nature of the malady, as it is safer to occasionally kill a creature that may be suffering from some other disease than to allow a tuberculous animal to escape.

LAWS OF NEW YORK.—By Authority. [Every law, unless a different time shall be prescribed therein, shall commence and take effect throughout the State, on and not before the twentieth day after the day of its final passage, as certified by the Secretary of State. Sec. 12, title 4, chap. 7, part 1, Revised Statutes.]

Chap. 487. An Act in relation to tuberculosis in milch-cows and other cattle, and infectious and contagious diseases of cattle. Approved by the Governor May 5, 1892. Passed, three-fifths being present.

The People of the State of New York, represented in the Senate and Assembly, do enact as follows:

Section 1. That the State Board of Health shall use all reasonable means for ascertaining the existence and cause of disease in, or danger to health from, milch-cows and other cattle in the State of New York, and for averting the same, and preventing all injury from tuberculosis in milch-cows or other cattle in any part of the State; and shall promptly cause all proper information in possession of said Board of Health, respecting any such disease among cattle in any part of the State, to be sent to the local Board of Health of the city, village, or town nearest to the herd, cows, or other cattle affected by any such disease, and shall add thereto such useful suggestions as to the removal of all sources of danger therefrom, or the destruction of said cattle, as the experience of the said board may at any time supply. And it is made the duty of the health authorities throughout the State to supply the like information and suggestions to the State Board of Health respecting the existence of any infectious or contagious disease in milch-cows or other cattle in any part of the State.

Sec. 2. The State Board of Health shall have power to employ such and so many medical and veterinary practitioners and other persons as it may from time to time deem necessary, to assist in the inspection, in the isolation, destruction, or disposition of milch-cows or other cattle affected with tuberculosis or any infectious or contagious disease in any portion of the State, to prescribe rules and regulations for such inspectors and employees, and to fix their compensation.

Sec. 3. Whenever tuberculosis shall be found among milch-cows or other cattle in any part of the State, it shall be the duty of the State Board of Health to take measures to suppress said disease promptly, to prevent the same from spreading, and the said State Board of Health shall have authority to order all persons to take such precautions against the spread of such disease as in the judgment of the said State Board of Health may be necessary or expedient; and further, to call upon all sheriffs, deputy sheriffs, and officers of the peace in the neighborhood where such disease extends among milch-cows or other cattle, to carry out and enforce the orders

of said Board of Health respecting the same, and to observe and carry out the rules and orders and instructions which they may receive from the said Board of Health in the premises; and further, to prescribe regulations for the destruction of animals affected with tuberculosis, or any contagious or infectious disease, and for the proper disposition of their hides and carcasses, and of all objects which might convey infection or contagion; provided, that no animal shall be destroyed unless first examined by a medical or veterinary practitioner in the employ of the State Board of Health aforesaid; and further, to prescribe rules and regulations for the disinfection of premises, buildings, boats, railroad cars, stables, and all objects from or by which infection or contagion may take place or be conveyed, and to alter and modify from time to time all such rules, regulations, orders, and instructions as the said State Board of Health may deem expedient.

Sec. 4. Whenever in the judgment of the said State Board of Health it may become necessary to prevent the spread of tuberculosis, or any infectious or contagious disease of domestic animals, or the public welfare shall be promoted thereby, the said Board of Health may cause to be slaughtered, and has authority to kill, or order to be killed, any animal or animals which by contact or cohabitation with diseased animals, or by exposure to infection or contagion therefrom, the said State Board of Health may consider and determine, may be liable to contract or communicate the disease sought to be suppressed, and to prevent all danger therefrom.

Sec. 5. Any person or persons refusing to obey the orders, rules, or regulations of the said Board of Health adopted in pursuance of the provisions of this act and the authority by this act given to the said State Board of Health, or transgressing the rules, orders, and regulations of the said State Board of Health adopted for the removal of the sources of danger from tuberculosis in milch-cows or other cattle, or any infectious or contagious disease in domestic animals in any part of the State, shall be guilty of a misdemeanor, and shall also be liable to pay a fine of one hundred dollars, which fine the State Board of Health is hereby authorized to sue for and collect in its name in any court of this State.

Sec. 6. All expenses incurred by the State Board of Health in carrying out the provisions of this act, and in performing the duties hereby devolved upon it, shall be audited by the Comptroller as other expenses of the said State Board of Health, and the sum of five thousand dollars, or so much thereof as may be necessary, is herewith appropriated out of any money in the treasury not otherwise appropriated for carrying out the provisions of this act.

Sec. 7. The actual value at the time they are killed, of any animals slaughtered, under the provisions of this law, to be ascertained and determined as hereinafter provided, may be paid to the owners of such cattle under and pursuant to any resolution of the said State Board of Health providing for such payment, and the Board of Claims shall have exclusive jurisdiction to hear, audit, and determine all claims which shall arise under the provisions of this act, and to allow thereon such sums as should be paid by the State; provided, however, that no compensation shall be made under the provisions of this act or otherwise to any person who shall wilfully have concealed the existence of disease among his animals, or upon his premises, or who shall in any way, directly or indirectly, by act or wilful neglect, have contributed to the spread of disease sought to be suppressed or prevented; and provided, further, that such claims shall not have accrued more than two years prior to the filing of the said claims.

Sec. 8. This act shall take effect immediately.

STATE OF NEW YORK, } ss.:
Office of the Secretary of State, }

I have compared the preceding with the original law on file in this office, and do hereby certify that the same is a correct transcript therefrom and of the whole of said original law.

FRANK RICE,
Secretary of State.

STATE OF RHODE ISLAND AND PROVIDENCE PLANTATIONS.—Chap. 1082. An Act in Amendment of Chap. 507, Chap. 627, Chap. 643, and Chap. 1025, of the Public Laws.

It is enacted by the General Assembly as follows:

Section 8. The board may appoint one cattle commissioner in each county of the State, whose duty it shall be to visit and inquire into the condition of any domestic animal in their respective counties whenever there is reason to suspect that any such animal is affected with tuberculosis, or other contagious, infectious, or communicable disease.

Sec. 9. The board may employ veterinary surgeons.

Sec. 10. Whenever any animal shall be suspected by either of the cattle commissioners to be affected with tuberculosis, the commissioner of the county where the animal is found shall immediately notify the secretary of the State Board of Agriculture, who shall promptly fix a day when the appraisers, duly appointed as hereinafter provided, shall visit the suspected animal with the veterinary surgeon; and upon confirmation of the disease, and after appraisement of the value as hereinafter provided, the affected animal shall be killed, and the carcass disposed of in such a manner as will not be detrimental to the public health.

Sec. 11. For the purposes aforesaid, the board may appoint some suitable person as appraiser, whose duty it shall be to act with one of the cattle commissioners in each county, which two persons shall constitute the board of appraisers for the county. In case of disagreement between the two appraisers, the veterinary surgeon shall act as a third appraiser, and the estimate of value of either two of them shall be final, provided that not more than $50 shall be allowed for any single native animal, nor more than $75 for any single grade animal, nor more than $100 for any single registered animal. And written notice of the amount of the appraisal, signed by the board of appraisers, shall be immediately given to the owner or claimant of said animal; and provided further that any party aggrieved by any award made under the provisions of this section may appeal therefrom to said board within five days after the receipt of said notice.

Sec. 12. The board of appraisers, by and with the advice of the veterinary surgeon, is hereby authorized to quarantine any animal or animals supposed to be affected with a contagious, infectious, or communicable disease, and one-third of the cost of such quarantining shall be assumed and paid by the State, except as otherwise provided in Section 21 of this act.

Sec. 13. The State shall pay to the owner of any animal killed under the provisions of Section 10 of this act, one-half of its appraised value; but if upon a post-mortem examination it shall be found that the slaughtered animal was not affected with tuberculosis, then the animal so killed shall be paid for at its full appraised value, provided that the State shall not pay for any diseased animal so killed if the animal has not been in the possession of its present owner three months previous to the day of the slaughter.

Sec. 14. When any person shall be shown to have knowingly brought into this State an animal suffering, or suspected to be suffering, with tuberculosis, or to have concealed the existence of such disease in any animal owned by him, such person shall not be entitled to any compensation for the animal slaughtered under this act, and shall be deemed guilty of a misdemeanor, and upon conviction shall be fined for such offence not exceeding one hundred dollars.

Sec. 16. No person having the care or custody of any animal having any one of the diseases mentioned in the preceding sections, shall, knowing the same to have any such disease, sell or exchange, or permit the removal, use or driving of the same upon any public highway, or the exposure of the same to contact with any other healthy animal of the same kind, except by permission of some member or agent of the State Board of Agriculture. Any person so doing shall be deemed guilty of a misdemeanor, and on being convicted, shall be fined not exceeding one hundred dollars.

Sec. 17. The State Board of Agriculture, or its duly authorized representatives, having reason to suspect the existence of any of the diseases mentioned in this act upon any grounds or premises, are hereby authorized and empowered to enter upon such grounds or premises for the enforcement of the provisions of this act

Sec. 18. The governor is hereby authorized to accept on behalf of the State the rules and regulations prepared by the Commissioner of Agriculture under and in pursuance of section 3 of an act of Congress, approved May 29, 1884, entitled: "An act for the establishment of a bureau of animal industry, to prevent the exportation of diseased cattle, and to provide means for the suppression and extirpation of pleuro-pneumonia and other contagious diseases among domestic animals," and to co-operate with the authorities of the United States in the provisions of said act.

Sec. 19. The inspectors of the bureau of animal industry of the United States, in co-operation with the State Board of Agriculture, shall have the right of inspection, quarantine, and condemnation of animals affected with any contagious, infectious, or communicable disease, or suspected to be so affected, or that have been exposed to any such disease, and for these purposes are hereby authorized and empowered to enter upon any grounds or premises. Said inspectors, in co-operation with the State Board of Agriculture, shall have the power to call on sheriffs, constables, and peace officers to assist them in the discharge of their duties in carrying out the provisions of the act of Congress approved May 29, 1884, establishing the bureau of animal industry; and it is hereby made the duty of sheriffs, constables, and peace officers to assist said inspectors when so requested; and said inspectors shall have the same power and protection as peace officers while engaged in the discharge of their duties.

Sec. 20. The State shall not be liable for any damages or expenses incurred under sections 18 and 19 of this act.

Sec. 21. Any person or persons who shall wilfully or intentionally interfere with any officer or officers, duly authorized to carry out the provisions of this act, or who shall wilfully or intentionally violate the provisions of the quarantine authorized by section 13 of this act, shall be deemed guilty of a misdemeanor, and upon conviction shall be liable to imprisonment not exceeding three months, or a fine not exceeding one hundred dollars, or both, at the discretion of the court.

Sec. 22. The State Board of Agriculture is hereby authorized to fix the compensation of the cattle commissioners, appraisers, and veterinary surgeons, to prescribe their duties and to remove them when deemed expedient so to do.

Sec. 23. The Secretary of the State Board of Agriculture shall make a monthly report to the governor of the obligations of the State Board of Agriculture; and the State Auditor is hereby directed to draw his orders on the general treasurer for the payment of the same upon vouchers approved by the governor.

Sec. 24. The sum of $15,000, or so much thereof as may be authorized, is hereby annually appropriated for the purpose of carrying out the several provisions of this act, including all salaries and expenses created under the authority hereof.

Sec. 25. All prosecutions for offences against the provisions of this Chapter shall be commenced within sixty days after the same shall have been committed, and not afterward.

Sec. 26. Chap. 507, Chap. 627, Chap. 643, and Chap. 1,025 of the Public Laws, and all acts and parts of acts inconsistent herewith, are hereby repealed, and this act shall take effect immediately upon its passage.

GLANDERS AND FARCY.—Glanders and farcy is the third form of the infective granulomata common to man and animals; it may be defined as a disease peculiar to solipeds, and transmissible from them to man and other animals.

It is very widely diffused and has been known from the earliest antiquity; it would appear, however, that some countries are more severely visited than others, and they are those where horses are most artificially maintained, and in which the laws of health are most imperfectly maintained or altogether ignored.

Liguistin, a French veterinarian, says that glanders was unknown in Mexico until the time of the Mexican war, in 1847, when the United States Army brought it to Vera Cruz; it is still rare, however, in its new home. It is very rare or unknown in Australia and India, is not infrequent at the Cape of Good Hope, and occurs in China. Great Britain and the Continent of Europe are much ravaged by it, and it occasions a great deal of mischief all over the United States.

The designations "Glanders" and "Farcy" are employed to distinguish two forms of one disease, that is, they seem to be two different diseases, but are in reality identical, however dissimilar in their external manifestations.

The term glanders is applied to the disease when the nasal or respiratory mucous membrane and adjacent lymphatic glands, as well as the lungs and other organs, are involved; and farcy, when the malady is localized in the skin and subcutaneous connective tissue, and secondarily in the lymphatic vessels and glands.

These two forms of affection may be observed in the same animal singly, simultaneously, or successively; and the virus of glanders may produce farcy by transmission from a diseased to a healthy animal, or farcy may in the same way produce glanders. Hence the name skin glanders (*Hautrotz*) given by the Germans to farcy is perfectly applicable.

Experimentation has shown that the morbid products of glanders and farcy, no matter from what organ or surface they are taken, give rise indifferently to one or the other form; and that the principal seat of the lesions of acute glanders, developed by inoculation, does not at all depend upon the source from which the inoculating material was derived; inoculation with the matter obtained from a glanderous pulmonary abscess may produce infection in which the principal, and sometimes only apparent, lesion is located in the nasal mucous membrane, and *vice versâ*. Again, material derived from a cutaneous abscess of acute farcy may occasion acute glanders, in which perhaps the most marked alterations will be found in the lungs or nasal passages, and *vice versâ*.

These facts prove glanders and farcy to be one and the same disease, no matter what organ, organs, or tissues appear to be more particularly affected.

Although glanders and farcy has been known to be a contagious disease for years, yet before the germ theory was thoroughly understood it was believed that under favorable conditions the malady might arise spontaneously in a horse, and that then he might transmit it to others. This was thought to be the case because it is sometimes impossible to trace an outbreak to its source, and this was an easy explanation for it; but now the belief is generally accepted that every germ must be the offspring of a pre-existing one, and that in order to have glanders develop in a horse, the specific virus must have gained an entrance to his system, even if the time at which he was exposed to infection is not known.

The causes of glanders, as of all communicable disorders, can be divided into the exciting cause and the predisposing causes.

The exciting cause of glanders has been discovered, within a few years, to be a bacillus, about the size of the tubercle bacillus, perhaps a trifle shorter and thicker. It has been studied chiefly by two German scientists, Loeffler and Shütz. It grows in a constant-temperature apparatus at 39° C. or 40° C. on sterilized blood-serum, or agar-agar; it also grows on sterilized cooked potato, on which it has a characteristic growth, forming brownish, gelatinous colonies.

After being carried on in pure cultivations for several generations it was found to still possess the power of producing the disease when inoculated into horses, rabbits, guinea-pigs, and field-mice.

It is hard to stain in sections, and has no characteristic stain like the tubercle bacillus, but in cover-glass preparations of cultures, the discharge from chancres or

pus from abscesses, it is readily stained by solutions of methylin blue.

The predisposing causes of glanders and farcy are similar to the predisposing causes in other diseases, that is, anything that depletes the system, renders it more liable to acquire disease; hence hard work, poor food, and bad hygienic surroundings are predisposing causes, as well as greater susceptibility on the part of some animals than others for some unknown reason, and also the free intermingling of animals, throwing them open to contagion. Glanders is almost certain to break out among army horses during a campaign. Here the privations, hardship, and work act as predisposing causes, and the diseased and healthy intermingle freely together, drink at the same troughs, and a healthy horse may be quartered to-night where a glandered one was last night. Invariably this disease causes great havoc among military horses during a war; it was rife among the horses used in the Crimea in 1854–56; in the war between France and Italy; in that against Austria; and in the Franco-German war in 1870. In the latter case the German cavalry took the field with magnificent horses that had been picked out carefully with especial reference to having them sound and healthy, yet it is said that not a single regiment returned without some of its horses being infected, and they spread it in Germany and Northern France to such an extent that, even to this day, it is said to be much more common on the Rhenish frontier than formerly.

In crowded, badly ventilated stables in large cities glanders spreads to a great extent if it once gets a foothold, especially if the work is hard, food poor, and the animals exposed to all kinds of weather. It is a question whether the beautiful public watering-troughs set up by benevolent hippo-philanthropists and noble humane societies may not assist in disseminating this disease if it is prevalent in a locality, healthy horses drinking after affected ones and becoming contaminated in this way.

Symptoms of Glanders and Farcy.—Clinically, glanders and farcy may be divided into four divisions: 1, Chronic glanders; 2, acute glanders; 3, chronic farcy; 4, acute farcy; and in studying the symptoms each form will have to be considered separately. This disease seems to take on an acute or chronic form depending upon the virulence of the virus, and the condition of the animal attacked, or its breed.

"Low-bred lymphatic horses being more apt to have the chronic form, while well-bred horses are more subject to the acute, although, as a rule, the chronic form is most common, but it may assume an acute character at any time.

"Chronic glanders may continue for months, and even for years, and the animals may exhibit but little constitutional disturbance, and yet be a source of constant danger to others with which they come in contact.

"The symptoms are local and general; the first are essential and constant, as well as contingent and accessory; the latter consists of more or less fever according to the duration of the disease and influencing circumstances.

"The essential characteristic local lesions are the nasal discharge, the ulceration of the pituitary membrane, and the enlargement of the submaxillary lymphatic glands. The disease usually commences with the symptoms of an ordinary acute or chronic catarrh from one or both nostrils, though it is said to be generally from one. The discharge, at first transparent and watery, later becomes opaque and sticky, collecting around the margin of the nostril, or being blown out in thick, lumpy masses.

"The discharge usually comes from the nostril in which the ulcers hereafter to be described are situated; when from both nostrils the ulceration is to be looked for in both of them. The older French veterinarians describe a form of the malady which they call 'Dry Glanders' (*morve sèche*), because there is no nasal discharge. It is extremely rare, however, that there is no discharge at all, a little serous slightly opaque fluid always flowing from the lower commissure of the nostril. In most instances at the commencement of chronic glanders the discharge from the nose is very slight, being produced by the ulcers that are just beginning to form · but if there be much inflammation of the mucous membrane, as there often is, then the discharge will be more copious, though less characteristic.

"The character of the discharge in chronic glanders, after the disease has existed for some time, is characteristic and not to be lost sight of as a symptom.

"It is glutinous, adhering to the skin around the opening of the nostril, forming soft, greasy-feeling crusts of a dark-brown color, which adhere to the fingers when touched; particles of straw, hay, hayseed, and the like are apt to adhere to the skin and hair, being held by this sticky discharge. At first it is chiefly albuminous, but it afterward becomes purulent, and then assumes a peculiar slightly greenish tint, which has been looked upon as a marked feature.

"If the disease has a tendency to assume an acute type, the ulcerations may cause slight hemorrhages, which cause the discharge to be streaked with blood, or else assume a rusty tint. As a rule the discharge has no odor, or it may have a slight sickish smell; it only has much fœtor when it accummulates in the sinuses of the head for some time, and is then due to putrefactive changes.

"The ulcers on the mucous membrane of the septum nasi or air-passages may be of two kinds: a true chancre, or simply a destruction in spots of the epithelium covering the mucous membrane.

"Only a small portion of the mucous membrane of the septum can be seen even when a careful examination is made, but sometimes the ulcers can be felt with the end of the finger above the reach of the eye, or they may be so far up as to be impossible of detection; in this case the character of the discharge and the enlarged submaxillary lymphatic glands have to serve as a guide in forming an opinion, with, in some instances, a knowledge of the history of the case.

"In chronic glanders the chancres are few in number, principally on the turbinated bones, and hard to find; it is possible, however, for them to be in plain view in both nostrils. What are to be chancres later first appear as small resisting points or 'nodosities,' varying in size from a millet-seed to a small pea; to the touch of the finger they feel like a small foreign body firmly fixed in the membrane; to the eye they appear as little round bodies of a yellowish color, surrounded by a pale, shining margin, or the margin may look red and inflamed the more nearly the disease approaches an acute type. They develop rapidly, often attaining their maximum size in a day. After three or four days the centre of the nodule becomes white and opaque, then breaking down, casting off the epithelium, allowing a drop of pus to escape, leaving a small concave depression; this is the first appearance of the glanders chancre, and constitutes confirmed glanders. At first this ulcer is somewhat circular, with a sharply defined border, finely notched around its margin, and roughened at the bottom.

"It is of a dull, leaden-gray color, occasionally streaked with blood-colored lines, or if the malady approaches the acute form it becomes bright red or violet-colored; invariably its margin is firm, hard, and slightly elevated, continuous with the fibroid base on which it rests. The chancre once formed may continue to ulcerate and extend, and may coalesce with others, forming a large irregularly shaped ulcerating surface; in proportion as the ulcer enlarges the induration of the mucous tissue becomes more extensive. The chancre may continue to suppurate, and the matter from it is often considerable in quantity compared with the size of the sore; not infrequently it coagulates and forms a yellow, but slightly attached crust over the ulcer. Occasionally the chancre may have a tendency to heal, it then contracts and fills up with granulations, which become covered with epithelium, the process forming a circular or stellate scar, its white color contrasting sharply with the natural color of the mucous membrane of the nose.

"In a stable of horses it is not rare to find one or more

with a small cicatrix or erosion in one nostril; these marks are perhaps due to a prick or scratch from a stub or similar foreign body, and should not be mistaken for chronic glanders chancres healed over.

"The healing process described above is probably the result of a check in the progress of the disease, and is an attempt of nature to restore the parts to a normal condition.

"But although the chancres in chronic glanders may sometimes heal, it by no means indicates perfect recovery, for the tubercles of glanders still remain in the lungs and are never absorbed, the body retains the virulent properties of the disease, which, although latent, will again become manifest at a future period by a second crop of chancres. In addition to the chancres in long-standing cases, there are frequently seen irregularly shaped erosions from which the epithelium has disappeared, as though it had been scraped off; they are usually observed upon the middle portion of the septum nasi, which is in this situation of a dull red color, has lost its shining appearance, and at times is covered with a purulent matter that is easily rubbed off. The third characteristic symptom of glanders consists in the enlargement of the submaxillary lymphatic glands, as the result of the action of the glanders poison upon them; this condition is always associated with the chancres in the nose, and the glands may be enlarged on one or both sides, depending on whether one or both nostrils contain the ulcers (hence the name of 'glanders,' given to the disease by the old farriers), the swollen gland being upon the same side as the nostril containing the ulcers. The gland is generally hard, nodulated, painless on pressure after the first few days, as a rule is rather immovable, adhering somewhat closely to the skin and structures over the jawbone. It is apt to be irregular in shape, usually oval, stretching from before backward, although it may be round and varying in size from a chestnut to a small apple, and generally has no tendency to soften and suppurate. Chronic glanders is sometimes accompanied or preceded by rheumatoid affections of the joints or sheaths of tendons, causing tumefaction of these and lameness, brittleness of bones, swelling of dependent parts, nose-bleed, cough, irregular respiration, and swelling of the sinuses of one side of the head, and the separate or collective presence of these symptoms may aid in diagnosing the disease when it is otherwise only suspected.

"The general symptoms accompanying these changes are, in the majority of cases, obscure at first; there may be observed a certain amount of fever, debility, and unthriftiness, with diminished appetite and loss of weight. When the appearances previously described commence to manifest themselves, there is a striking recovery apparently, the appetite is regained, the animal becomes lively, improves in condition and general appearance, as if a crisis had been passed and recovery was assured.

"This deceptive state may continue for some months, and it is only in those cases in which the disease is localized in the lungs from the commencement, and generally when the malady is of long standing, that the animal continues to look ill, and the above-enumerated general symptoms persist.

"Usually, notwithstanding the apparent healthiness, or check of the disease, it goes on extending its ravages, and at more or less distant intervals is complicated by exacerbations, which promptly increase the lesions. Some of the exacerbations are at times so severe that the animal may die of acute glanders in a few days; indeed, the malady nearly always terminates in this manner, as its progress is generally all the more rapid the older it is, as though the acute type had suddenly appeared. Then come the frequent cough, difficult breathing, swelling of the extremities and dependent parts in general, or farcy tumors or ulcers appear in different regions; and finally death follows from marasmus, or rapid formation of glanderous abscesses, accompanied by intense fever or pyæmia" (Fleming's "Veterinary Science and Police").

Although the classical symptoms of glanders are the chancre, discharge from the nose, and enlarged submaxillary glands, yet it is not infrequent for one or more of these symptoms to be absent, and there may be cases where glanders tubercles exist in the lungs without any external manifestation of the disease being present; the horse after death is found to have the lungs full of glanders nodules in various stages of development, from the new translucent nodule to the calcareous one, with intermediate forms in different states of caseation. This form is called internal or pulmonary glanders. The nodules may also be found in the liver, spleen, bronchial and mesenteric glands, and similar locations. These cases are the most dangerous, as such horses are capable of transmitting the disease to others, yet during life they show no symptoms by which even veterinary experts can make a diagnosis, unless an animal may be suspected for some reason in a stable where glanders exists.

Acute Glanders.—Glanders may assume an acute form at the outset, or chronic glanders may terminate by assuming an acute character. Here, as in chronic glanders, the symptoms are general and local. The general symptoms are loss of, or capricious appetite, a staring, unthrifty-looking coat, and high fever; the temperature is said to have reached 109° F., according to Trasbot, a French observer; at all events it reaches 106° to 107° F. (the normal temperature of the horse is 100° F.); the fever lasts several days and there is rapid emaciation.

The animal sweats on the slightest exertion, the subsequent lassitude is very marked, and there are shiverings and tremblings, and perhaps sudden lameness without any appreciable cause. The urine is increased in quantity and of a low specific gravity, and it is said may contain albumin; the breathing is hurried and irregular, occasionally being as high as forty or fifty respirations to the minute, and may be accompanied by a snoring sound, and dyspnœa almost amounting to suffocation. The pulse is small and quick, and the artery soft and flaccid. The visible mucous membranes are highly congested, of a yellowish hue at first, later becoming darker-colored until almost purple, when suffocation is imminent. The nasal mucous membrane is highly congested, appears thickened, and there may be hæmorrhage from it.

After a few days the fever subsides, and as it disappears the local and essential lesions commence to manifest themselves, their appearance being coincident with the decrease in fever, although the temperature does not become normal but remains at about 102° F.

The glanders nodosities then appear upon the pituitary membrane resembling those described as belonging to chronic glanders, except that in the acute form there is a red zone around the nodule. In a few days these points break down, leaving a granulating ulcer of a reddish-violet hue, having a ragged salient border, and a tendency to bleed easily when touched. The chancres are numerous, irregular in shape, and rapidly invade the membrane, often becoming confluent, forming great ulcerating sores of various sizes and outlines, which may penetrate to the cartilage, and even lead to necrosis of it, sometimes even causing perforation of the septum if the animal lives long enough; the ulcerative process may also extend to the larynx and trachea. Following the formation of the ulcers comes the characteristic discharge, thin and watery at first, later becoming thick and sticky, or streaked with blood.

Then, as a result of the passage of the virus through the lymph-vessels, the submaxillary lymphatic glands enlarge, being soft and painful at first, later becoming hard and adherent and free from pain.

Farcy in an acute form (Fleming) nearly always complicates acute glanders, just preceding it, accompanying it, or following it; in addition, lymphatic vessels in different parts of the body become inflamed, depending parts become œdematous, even the head around the nose. Respiration may be harsh and difficult from the ulceration of the larynx.

The fever, which had almost disappeared when the eruption broke out, returns; the lungs may be inflamed from a lobular pneumonia or from the formation of nodules; new ulcers are continually forming on the skin and on the septum nasi, and suppurate freely; emaciation is very

rapid, and a profuse diarrhœa may appear toward the end.

In acute glanders death occurs from eight to fifteen days after the appearance of the fever, and is due either to exhaustion, to asphyxia when the larynx is severely involved (in which case it may occur earlier), or in consequence of the amount of lung involved in the process.

Chronic Farcy.—Farcy, like glanders, can be divided into two forms—the chronic and the acute—and may exist by itself or be associated with glanders.

Chronic farcy is considered the least serious form of glanders; though it is, Fleming asserts, the most frequent. This is not the writer's experience. As far as he has been able to observe in this country, farcy is rare in comparison with glanders, and usually the cases of farcy he has seen have been associated with glanders.

As in the other forms of the disorder there are local specific lesions, and also the general symptoms.

The local lesions consist in the appearance of superficial indolent tumors, especially along the course of the lymphatic vessels on the inside of the hind- or fore-leg, called "farcy buds." These soon ulcerate and become chancres, constituting the specific feature of the malady. These tumors may vary in size from a pea to a small nut, may appear in the skin first, and later extend into the subcutaneous connective tissue, or may appear first in the subcutaneous connective tissue, and later extend to the skin; the small ones are generally in the skin, and the large ones commonly in the subcutaneous connective tissue, invading the skin only when they begin to ulcerate. Either form may occur as isolated lumps, or in groups, or the latter may become confluent over a limited surface. Besides appearing on the inside of the legs these tumors and ulcers may develop anywhere upon the body, although they generally appear where the skin is thinnest and most vascular, next to the insides of the legs coming most frequently around the eyes, nostrils, lips, and upon the face, in the jugular space, on the chest, abdomen, shoulders, flanks, and near the root of the tail.

Their number is very variable. First one and then another of the nodules may appear, followed by one or two more, invading the system gradually, or a large number may develop all at once.

Much depends upon the general health of the animal, and the severity of the attack at first; when it appears with first one bud, and then another develops, it may be several weeks, or possibly months, before the horse becomes badly diseased. After the appearance of the nodules under the skin, which at first feel like small, hard points, that may sometimes disappear to appear again in other situations; they finally increase in size, soften at the centre and break down. From this small abscess there flows a little thin, yellow, oily, purulent material, which is very characteristic of the disease, leaving a chancrous ulcer, appearing as a concave excavation of a dirty yellow or grayish color, with an indurated margin and base. It secretes considerable pus, which may coagulate upon the surrounding hair, forming a yellowish crust over the ulcer, which can, however, be easily rubbed off with the finger. The farcy ulcer has no tendency to heal, and may extend by destroying the tissue around its margin; if near together, several chancres may become confluent, forming a large, irregularly shaped sore. No matter how irregular in shape the ulcer may be, it retains certain specific characteristics that are never lacking, and that are diagnostic: the character of the secretion, the peculiar jagged border, the surrounding induration and hard base, as well as the marked depression in the centre of the sore, are to the experienced eye unmistakable evidences of chronic farcy.

Following the development of the farcy buds, within a few days cord-like swellings appear, leading from the ulcers toward the nearest lymphatic glands; these are inflamed lymphatic vessels, and are called "farcy cords." At first there is a diffuse swelling around them, but in three or four days they become well defined, are hard to the touch, and about the size of a goose-quill.

This corded condition of the lymphatic vessels soon changes, and at certain distances along their course little enlargements appear, giving them a beaded appearance; these enlargements soften in the centre, break down and form new chancres; this is the result of the action of the glanders virus upon the lymphatics, the new buds probably forming at valves in the vessel, where the virus has a chance to rest and cause the production of buds, followed by ulcers. The chancres may extend until the cord is transformed into a chain of sores, which may even coalesce, forming a long, linear, ulcerating furrow.

Occasionally these secondary ulcerations may attempt to cicatrize, but when they do form granulation tissue it is soft, spongy, and easily torn. Very rarely the primary buds from which the cords emanate may disappear or cicatrize, in which case the cords, instead of forming secondary buds, may partially subside, or even regain their normal condition. This state of affairs, which is very infrequent, would appear to mark a check in the course of the malady, and lead to the hope that it is about to terminate in recovery, but in too many instances the improvement proves to be only temporary, and the disease again shows itself, sooner or later.

In chronic farcy the lymphatic glands may later become swollen, as the result of the farcy cords carrying the poison from the farcy buds to them. These glands may be in various locations, depending upon the proximity of the farcy buds to them, and have the same characteristics as the submaxillary glands in glanders.

In chronic farcy there may also occur swellings and tumors; the latter are rather rare, consist of swellings on various parts of the animal, varying in size from a hen's egg to a man's fist. At first hard, hot, and painful, they in a few days soften and fluctuate; then, if lanced, they discharge matter resembling that from a farcy bud, and continue to discharge, with little tendency to heal; or the lips of the wound may heal together so that the cyst or abscess is re-established, or complete healing from the bottom may occur.

The farcinous swellings are of an inflammatory nature, and appear on the limbs, generally the hind ones; they may occur around a joint only, as the hock, fetlock, or knee, or there may be a diffuse swelling of the entire leg, the limb being very much swollen, and the animal evincing great pain and lameness in it. Sometimes the lameness may appear before any swelling, and this lameness is very often coincident with the first appearance of the disease; hence lameness is often the first manifestation of glanders or farcy, even before any other symptoms appear. On the other hand, swelling of the limbs or obscure lameness is by no means a constant symptom. The tumefaction of a limb may be persistent or it may more rarely subside in a few days; but this subsidence is coincident with the appearance of the disease.

The eruption of farcy is always accompanied by fever, or else preceded by it; but this might easily escape the attention of an ordinary observer.

Chronic farcy is then characterized by "buds" or chancres on the skin, these yielding a peculiar pus; by swellings which may, or may not, be followed by ulceration of the contiguous lymphatic vessels; and by non-suppurating, non-ulcerating swellings of the lymphatic glands in which the vessels terminate.

Acute Farcy.—Like chronic farcy the acute form has the local and general symptoms; it resembles the chronic form, varying from it chiefly in degree. It is ushered in by well-marked symptoms, the animal is very feverish, refuses its food, and has all the signs of general constitutional disturbance noticed in acute glanders. After two or three days the fever subsides, the patient appears to be better, and regains its appetite and spirits; but in a few days the fever reappears, the pathological changes become general and rapidly reach their last stage. The farcy buds appear very suddenly, are more numerous, develop more rapidly, and ulcerate earlier than in chronic farcy. Fleming says that the "buds" may attain the size of a large nut and soften in the centre, ready to ulcerate during a single night. The legs may be swollen to an enormous size, and are then very painful. Each bud ulcerates toward the second or third day, the ulcer being wide and deep, and extends

rapidly. The matter from them is abundant and viscid, often wine-colored or streaked with blood. The chancres may be covered with exuberant purplish granulations, which may bleed at the touch; the ulcerations extend rapidly and may become confluent with others, forming large unhealthy looking sores, which may be bright red at points, or covered with brownish crusts.

The "farcy cords," so-called, develop rapidly, soon break down, forming secondary chancres, and may become a sloughing furrow from which exudes an abundant quantity of a sticky, blood-tinged pus. The lymphatic glands to which these vessels lead swell rapidly and are very painful to the touch, but have the usual characteristics of the glands in glanders.

In acute as in chronic farcy there are other symptoms than those already described, which although not exactly characteristic of the disease, are at the same time often present; these are the swellings of dependent parts of the body and limbs, and obscure lameness.

While these changes are going on, the fever continues with intermittent exacerbations; symptoms of acute glanders soon appear, the animals lose flesh rapidly, sink into a state of exhaustion, and soon die, if not killed before they reach this point.

From what has already been said it can be seen that, as a rule, any form of glanders is fatal in time. Fleming, in his "Sanitary Science and Police," whose classification and descriptions have been closely followed above, says that chronic glanders is more common in the horse, and that the acute type more frequently attacks the ass and mule, while, on the contrary, farcy is more likely to be acute in the horse and chronic in the ass and mule.

Farcy was formerly considered curable in equines; hence the distinction of glanders and farcy as two distinct diseases by the old writers, and it may be that in some instances this distinction is still made; but owing to the danger from a farcied horse to man and other equines, treatment is not permissible, and in most of the Northern States the law requires that all glandered and farcied solipeds must be killed; but in some of the Southern and Southwestern States there is a woful lack of sanitary legislation, and glanders and similar diseases are permitted to run riot without any attempt to check their ravages.

Diagnosis.—From the symptoms described above it can be readily seen that a typical case of glanders or farcy is not hard to diagnose, but there are cases where it is a very difficult matter if one or more symptoms are lacking. In such cases depleting the horse's system will sometimes cause the disease to develop more rapidly, and in this way enough evidences of the disease may be obtained on which to base a diagnosis. This is best done by giving the animal a powerful cathartic, thus depleting the system so that it has less power of resisting the invasion of the disease.

Inoculating another animal may be resorted to for the purpose of deciding an uncertain case. For example, a valuable horse may be suspected of having glanders, yet it is doubtful whether he has or not; in such a case an ass, or an old horse—preferably the former as being more susceptible—may be inoculated with some of the nasal discharge or exudate from a farcy sore, and if the inoculated animal develops glanders or farcy it is evident that the one from which the virus was taken has the disease; but if the inoculated animal does not have it, it does not always prove the health of the first, but may show the insusceptibility of the latter, although as a rule the test may be considered tolerably reliable. Guinea-pigs may be used for inoculation tests, as they are quite susceptible, and will develop the malady in eight or ten days, and die of it in six or eight weeks. Or, if the investigator has time and is enough of a bacteriologist to do so, he might try cultivating the bacillus on potato, and then inoculate guinea-pigs from the cultures.

The suspected horse should be quarantined, isolated from other horses, and should have a separate water-pail, separate currycomb and brush, etc. The attendant must not allow any secretion of a glanderous character to come in contact with a cut or scratch on his skin, and it is very dangerous, should a horse cough or blow any glanderous discharge into the nose, eyes, or mouth of a person.

There are various maladies of the horse that may resemble glanders for a while; here it is best to wait a few days and watch the course and development of the sickness, when it can soon be told whether the trouble is glanders or not. Some of the ailments that may simulate glanders are strangles, chronic nasal catarrh, or a discharge from the nose caused by a diseased upper molar. In various conditions where glanders is suspected, if the animal is kept under observation for a few days it will soon become evident whether he has the disease or not, with a few rare exceptions. Horse-pox may resemble glanders for a few days, and the scars left from sloughs on the pituitary membrane may sometimes resemble slightly the cicatrices of the ulcers in chronic glanders.

Chronic or acute farcy may be difficult at first to differentiate from lymphangitis, horse-pox, or other diseases causing much inflammatory swelling of the legs; here again a waiting policy is to be adopted for a few days, in order to ascertain what the leg does; observe whether sores upon them cicatrize, or whether they are chancrous; notice also whether the discharge from them is characteristic or not.

In considering the diagnosis of glanders, it would not be complete without a brief mention of mallein as an aid to diagnosis in doubtful cases. Mallein is a chemical product of cultures of the glanders bacillus, obtained by making a sterilized glycerine extract in the same way as Koch's tuberculin is prepared from cultures of the tubercle bacillus. It was first made by Kalning, a Russian veterinary surgeon, who conceived the idea from Koch's discovery of and experiments with tuberculin.

It is used as a subcutaneous injection in doses of two and a half c.c. of a ten per cent. solution, and is said to produce a reaction in glandered horses similar to the effect said to be produced in tuberculous cows by tuberculin, without having any marked effect on a healthy horse. It has been experimented with more extensively than tuberculin, and its effects so far seem to be more certain.

If the animal be glandered, there is a marked local swelling at the point of inoculation, hot and painful to the touch, and the temperature rises three or four degrees, the rise commencing in three or four hours, attaining its maximum in about ten hours, and remaining so until the expiration of from eighteen to twenty-four hours, when it gradually subsides. All the evidence at present obtainable points to mallein as a valuable diagnostic agent in suspected cases of glanders, and if all that is said of it be true it promises to become an invaluable aid in the confirmation of doubtful cases of this disease.

It can be obtained from the Pasteur Institute, in Paris, and the Bureau of Animal Industry, of the United States Department of Agriculture, also had a little to spare at one time, and may still have some.

Prognosis.—From what has already been said it is easy to see that the termination of glanders and farcy *must* be fatal, and as the disease is so dangerous, treatment, except in the case of man, is not allowable.

In man, if it is realized at once that he has become inoculated with glanders in any way, the point of inoculation should be thoroughly cauterized with the actual cautery, or if this is not possible, with the nitrate of silver. The treatment farther than this is, like the modern treatment of syphilis, mercury and iodide of potash, together with the hot baths which in some parts of the country seem to have a medicinal effect.

In the human the disease is not always diagnosed in time, as it occurs so infrequently in man that physicians do not in every instance recognize it at once, particularly if there happens to be no obtainable history of the case to aid in ascertaining what the trouble is.

Prophylactic treatment is then the only kind to follow in outbreaks of glanders and farcy.

Diseased animals should be killed, and their carcasses destroyed at once. Near our large cities the horses killed for this disease can be taken to large rendering establish-

ments, and the process of rendering destroys the germs of the disease. In the country the infected animal should either be cremated, or buried very deep, the remains covered with quick-lime before shovelling the earth in on top of them.

The stall where the glandered animal stood should be thoroughly disinfected; this can be done by using boiling-hot water, or going over the stall with a whitewash brush and a solution of corrosive sublimate 1 to 1,000, or a strong solution of sulphate of copper, afterward whitewashing the stall.

Woodwork on which the horse may have distributed much virus, such as the manger, rack, and floor, should be torn out and burned and replaced by new. His pail, halter, and blankets should also go into the bonfire, unless the blankets will stand boiling for twenty minutes to half an hour without being ruined. Saddles should have the lining taken out and burned, bits should be boiled, and harness cleaned with very hot water and soap. The curry-comb and brush should be burned.

In this way, removing the diseased animal or animals, and thoroughly disinfecting after them, an outbreak may be nipped in the bud; but for some weeks, or even for several months, all the horses in the stable should be kept under careful observation, and if a horse presents any suspicious symptoms he should be at once isolated and kept watch of until the symptoms either entirely disappear, or the disease develops enough to justify his slaughter. A horse thus isolated must not be allowed to come in contact with the others in any way, he must not drink at the trough with them, but have a pail exclusively for his own use; the currycomb and brush used on him must not be used on other animals, and his blankets and halter are for his use only. The moment there is no doubt as to his disease being glanders he should be killed, and the safeguards against the spread of the disease already described immediately adopted. Glanders is what is ordinarily spoken of as a contagious disease, that is, it is usually communicated by actual contact between diseased and healthy animals, but the germs may also be carried by some intermediary body, such as the woodwork, if a healthy horse is tied in a stall where an infected animal has been kept, or if he drinks constantly from the same trough with a diseased horse; the disease can also be carried from an affected to a healthy animal by means of the currycomb and brush, the virus on the implements entering through an abrasion of the skin. The virus may blow around in the dust of the air, but there is less danger from this source than in most communicable diseases, as the discharge containing the bacilli is sticky and apt to remain where it fell, and does not dry up and blow around readily, especially if the stable be at all damp.

Persons employed in taking care of glandered horses must be very neat and clean, particular not to get any discharge on the clothes or hands, and if they do not feel well, or have any sores appear on the face or hands, they should at once consult a physician.

In making post-mortem examinations of glandered animals care must be taken not to cut or scratch the hands, and a person with a cut or sore on the hand should under no circumstances make an autopsy upon a horse with this disease. The virus, so-called, is the material containing the bacilli, and they may be present in the pus from ulcers in the nose, from farcy sores, from nodules in the lungs, and may exist in the other lesions, besides being carried in the lymph-stream, and possibly in the blood also.

The vitality of the virus of glanders is considerable. Fleming says that instances are known where horses have contracted glanders and farcy in stables where the disease had existed, but in which no horses had been kept for periods of from six to twelve months prior to the introduction of healthy ones.

The disease is one peculiar to solipeds and is transmissible from them to various species of animals, although some are more susceptible than others. The degree of susceptibility also varies in different horses, some showing a much greater predisposition than others. Next to solipeds in susceptibility to glanders come the feline, canine, and human species, in the order named.

Sheep and goats may have this malady, the sheep taking it more readily than the goat. Bovines and swine are so difficult to infect that it can be said that they practically enjoy immunity

Guinea-pigs, as already mentioned, are easily infected and are of value for inoculation-tests of glanders and farcy. In Europe this disease has been observed in zoölogical gardens among some of the larger carnivora, such as lions and tigers, that have received the flesh of horses killed for glanders as their food.

The symptoms of glanders and farcy in other species of animals than the horse resemble the disease in him; that is, there is the same ulcerated condition of the mucous membrane of the air-passages, as the septum nasi, turbinated bones, larynx, and trachea, with the same viscid purulent discharge from the ulcerated surfaces, besides the enlarged lymphatic glands and the formation of nodules in the lungs, and perhaps in other internal viscera as well. Or if the malady assume the type known as farcy, the "farcy buds," "farcy cords," cutaneous chancres, and enlarged contiguous lymphatic glands may all be present.

The Post-mortem Appearances in Glanders.—In making an autopsy upon an animal which has died of glanders, or been killed on account of the disease, the nasal passages should first be examined. (This can be done by removing the inferior maxillary bone and its soft attachments, then sawing the head in two transversely just below the eyes; then saw off the pre-maxillary bone; after which, if the part of the head thus separated be divided longitudinally a little to one side of the median line, one nasal cavity is opened, exposing the septum on one side and the turbinated bones on the other. To examine the other half of the nasal cavity the septum can be removed with a sharp cartilage knife, when its other side and the turbinated bones in the other nasal chamber are laid bare for inspection.) If the horse had glanders the ulcers and cicatrices previously described will be found upon them, although they may have been too high up in the animal's head to have been seen during life. The submaxillary glands—or, in fact, any enlarged lymphatic gland in this disease, for all resemble each other no matter where situated—are at first swollen and inflamed and full of a yellow, citron-colored lymph; later, they may contain little cavities holding a yellowish, greasy pus, resembling the fresh pus from the chancres, and when older still this pus becomes cheesy, and later even calcareous.

"Farcy cords," when cut into, are found to be lymphatic vessels with thickened walls; the lymph in them is at first thicker than usual and somewhat opaque, later still it may become purulent. Fibrinous clots may also be found, upon post-mortem examination, in the superficial veins of the farcied leg or in the pulmonary veins, in cases of acute glanders.

In the lungs nodules are found resembling tubercles, but they are more vascular than the nodules in tuberculosis, and hence have less tendency to break down at their centres early; but later they may soften and contain the characteristic pus, which in time may become cheesy or even calcareous. The nodules of glanders are rarely found to be calcareous, as the animal usually dies or is killed before this stage is reached.

The purulent material from the chancres, nodules, etc., contains the germs of the disease. Ulcers in the larynx and trachea may also be found, and may even extend in an unbroken line from the larynx to the lungs.

Microscopically, the nodules of glanders, like the lesions found in all the diseases of this class (the infective granulomata), are found to be made up of granulation tissue. The granulation tissue in glanders is composed of a small, round-celled growth, which on free surfaces has a tendency to break down readily, forming ulcers, but in other situations forms nodules, the centres of which may soften and contain a few drops of pus. These lesions are due to the specific cause of the disease, the glanders bacillus.

Glanders nodules may also be looked for in the liver,

spleen, mediastinal and mesenteric lymphatics, and also in the intestinal walls, but are rarely found in any of these last-named organs.

The number of nodules in one set of organs is very apt to depend on the number in another set, in an inverse ratio; that is, if a great many chancres are found in the nasal cavities, but few nodules are likely to be present in the lungs, and *vice versâ*.

Glanders completes the list of the infective granulomata which may affect the lower animals. The two most important diseases remaining that may occur among our domestic animals and be communicated from them to the human species, are rabies and anthrax. A consideration of the former will first be taken up.

RABIES.—Rabies is a disease peculiar to the canine species, and is communicable by inoculation from them to man and other animals.

In natural infection, inoculation takes place by means of bites, the saliva being the medium for bearing the virus. The disease can also be produced by experimental inoculation, the medulla and upper part of the spinal cord being beaten up in a sterilized fluid, preferably veal broth, and some of the liquid injected under the skin of any small animal with a hypodermic syringe; or results may be obtained several days sooner by trephining the skull of the experimental animal and injecting a few drops under the dura mater, bringing the virus in much speedier contact with the nerve-centres.

The germ of rabies has not yet been demonstrated, except by means of inoculation experiments.

Rabies is derived from the Latin, meaning madness or raving; the malady is also popularly known as hydrophobia, but this term is clearly a misnomer, as in the dog there is no fear of water, but simply an inability to swallow, due to paralysis of the throat; the suffering animal will attempt to drink, but its efforts to lap water bring on a spasm which is pitiful to see. If a person with rabies evinces a fear of water, it is nothing more than the effect of a popular fallacy upon the imagination.

This disorder has been known since the earliest antiquity; it is mentioned in the writings of Homer, Hippocrates, Democritus, and Aristotle, and later by many authors, both physicians and veterinarians.

Rabies may occur among all members of the canine family, and in Europe a number of outbreaks have occurred among wolves; under such circumstances they may become very ferocious and may attack and bite people; a bite from a rabid wolf is said to be more dangerous than the bite of a mad dog. Blaine says that in 1271 there was a serious epizoötic of this disease among the wolves in Franconia; in this outbreak they became very savage and attacked humans in preference to anything else; many people were bitten, and upward of thirty men are said to have died of rabies at this time. In 1590 there was another epizoötic of this malady among wolves in the province of Montbelliard.

It is unknown in New Zealand and Australia; in the latter country all dogs imported to the colonies are quarantined for six months, and in this way rabies has been prevented from ever gaining access to this part of the world.

Causes of Rabies.—Like all contagious diseases, one case must come from a pre-existing one, and the theory that it can arise spontaneously is not tenable in this enlightened age. Formerly many incorrect views were held regarding its origin, such as, that it was caused by want of water; or by excessively hot weather; or by ungratified sexual desire. Some canine philanthropists, even at the present day, assert that no such disease as rabies exists at all; this view is incorrect, and it is needless to argue the point here farther than to say, that because officers of anti-cruelty societies and professional dog fanciers do not believe in the existence of rabies, or think that muzzling dogs is cruel, it is no reason that such a disease does not exist; and what they have to say on the subject should be taken for just what it is worth—that is, nothing.

It must be admitted, however, that many people that die because they are bitten by so-called "mad dogs," depart this life as a result of fright; this is always the case where the newspaper victim succumbs "in horrible agony twenty-four hours after being bitten by the rabid monster," as the incubative stage of rabies covers a period of at least three weeks after the bite takes place, and is more likely to be from one to two months in length.

Another popular idea is that rabies occurs less frequently in the bitch than in the dog; the reason for this is due to the fact that there are very few bitches kept in comparison to the number of dogs.

Like all contagious diseases, it is liable to lulls and outbreaks; it may be unheard of in a locality for a number of years, then it will be quite prevalent for several seasons, and will again subside for a period of greater or lesser duration.

This is shown by the vital statistics of Massachusetts, going back over a period of several years. In 1876 there were four human deaths from rabies; in 1877 fourteen, in 1878 fifteen; then it gradually subsided, there being five in 1879, three in 1880, three in 1881, and then none until 1888, when there were two; then it increased rapidly, there being fourteen in 1889, seventeen in 1890; then it began gradually to subside again, there being only nine in 1891. Before 1876 there were no cases in humans after 1870, when two deaths occurred.

If a record of the vital statistics of animals were obtainable, it would be found that the deaths among humans bore a direct relationship to the frequency of rabies among dogs, and that when there is an outbreak of this disorder among our canine pets covering three or four seasons, the fatalities among people from this cause correspond to the canine epizoötic, or enzoötic; and as it disappears among the animals, deaths from it among humans cease to be reported as frequently, and finally not at all, until the malady reappears again after a lull of several years.

It would be a matter of great utility if veterinarians (that is, qualified veterinarians) were required to make returns to the registrar of vital statistics of the contagious diseases that occur in their practice among animals. These returns could be tabulated, and although they might not be complete, yet they would show to some extent the relative frequency of the same diseases among men and animals in certain localities, and for this reason would prove of great interest and value.

That rabies is peculiarly a disease of the summer months, or a result of excessively hot weather, is easily disproved by almost any statistics upon the matter that one chooses to consult. For example, if the vital statistics of Massachusetts be referred to, it will be found that the cases of human rabies for several seasons occurred as follows:

For 1889.		For 1890.		For 1891.	
January	1	February	1	February	2
April	2	March	3	April	1
July	1	April	3	August	2
August	3	May	2	September	2
October	3	June	3	October	1
November	3	July	2	November	1
December	1	September	1		
		October	1		
		November	1		
	14		17		9

Of the persons bitten in 1890 in Massachusetts, fourteen were males, three were females, two were children under three years of age, five between five and ten, and all but four were under twenty. In 1891, all the persons bitten, or rather reported to have died of rabies, in Massachusetts, were males. These figures prove little beyond the fact that males have more to do with dogs than females, that the clothes of females perhaps afford more protection from dog bites than those of males, and that little children do not know enough, or are not able, to avoid a rabid dog as easily as an adult.

In a consideration of the pathology of rabies there are, according to Williams, three interesting peculiarities worthy of notice:

"First. The period of latency is very indefinite." Some veterinary authorities give the shortest time in which rabies can develop in the dog after being bitten as

seven days, and it is said to vary from this up to twelve or fourteen months after the infliction of the wound, in a few very rare instances. Repeated inoculation experiments in rabbits performed by trephining, however, show that rabies develops in them with a fair degree of constancy in from eight to twelve days; it is therefore very doubtful if it can develop in any animal by means of a bite in such a short space as seven days; certain it is, on the other hand, that in very exceptional cases the period of latency may extend over several months, even to the end of a year's duration. As a rule, however, it may be said that rabies develops in from twenty-one to thirty-five days after the infliction of the bite, that very rarely it may appear in from fifteen to seventeen days, and that if no symptoms develop at the end of sixty days the danger may be looked upon as very slight, and after ninety days it can scarcely be considered to exist at all.

"Fleming, in his 'Veterinary Science and Police,' quotes Haubner as reporting two hundred cases in which the disease appeared within two months of the bite in eighty-three per cent., between two and three months in sixteen per cent.; the other one per cent. occurred within four months.

"Second. The bite of the rabid animal does not always produce the disease" (Williams). This may occur if the saliva does not enter the wound inflicted by the teeth. For example, a rabid dog may bite a person through the clothing, thus wiping the virus from the teeth before breaking the skin, or he may attack a flock of sheep and the wool will clean his teeth so that only the first two or three bitten will develop rabies and the rest will escape. Bites upon the unprotected parts of the person are always the most dangerous, such as those inflicted upon the bare arms or hands, through the stocking, or particularly upon the neck and face. Rabies is also said to develop earlier from a bite upon the neck or face; this may be because the wound is situated nearer the great nerve-centres.

"Third. The disease is not transmissible to man, mammifers, or birds by the usual media at a period later than twenty-four hours after the death of the rabid animal, or after the cadaveric rigidity (*rigor mortis*) has completely invaded the body" (Williams). This is hardly a modern idea, and while it may be true of the saliva, blood, and the like, it is not true of the nervous centres, where the seat of the disease is now believed to be. Rabid rabbits may be kept after their death in a freezing temperature for months, and the medulla and cord are still found to be active if used for inoculation tests; but the germ is easily killed by heat, as, if the frozen rabbit be put in a steam sterilizing apparatus in order to hasten the thawing process, it will be found that the virus has lost its activity if the dead animal be subjected to enough heat to parboil the tips of its ears.

If, however, the medulla and upper part of the cord be removed from the rabid rabbit and be hung in a perfectly dry atmosphere, in a cool place, for ten or twelve days, it will lose its active properties; this is Pasteur's method of attenuating the virus to be used in protective inoculation against this disease.

Symptoms of Rabies.—There may be premonitory signs, such as pain at the seat of the bite, melancholy, irritability, febrile disturbance, or stiffness about the head and neck; these symptoms are however not generally noticed in the lower animals. In the dog the first symptoms to be noticed, as a rule, are that he is dull, restless, avoiding companions and shunning light; he is also often disposed to hide away in corners, behind chairs, under tables, and in similar places. He may become fidgety or easily excited, and often has a tendency to try and escape and wander about the country, and may at this roving period have a tendency to bite other dogs, animals, or men, and at this time is very dangerous. In short, there is a variable train of nervous symptoms that may affect him in different ways, and of gradually increasing severity. At first he knows his owner and will recognize and obey him even when acting peculiarly; the disposition is often changed—for example, a fierce dog may become playful and good-natured, while an animal formerly noted for his kindness may become savage and snappish. The appetite frequently becomes capricious or morbid, he refuses his food, and may have a tendency to pick up and swallow stones, bits of leather, feathers, and such substances. Later, he may have hallucinations, and may be noticed snapping at imaginary flies, or objects that exist only in his imagination. At first he drinks water with little or no difficulty, but later, when the throat becomes paralyzed, he is unable to do so, and when the attempt is made it brings on a peculiar paroxysm: the animal shudders, staggers back, and in advanced stages even falls; this seems to be accompanied with a spasm of the larynx. In some cases he may vomit, and the vomitus may be tinged with blood. A paralysis develops, the lower jaw drops, and it will be noticed that the tongue is coated, and that both the tongue and inside of the mouth have a curious dark reddish-brown appearance, and the breath is also said to be fetid.

It is said that in the human subject, in the early stages of rabies, there is a little vesicular eruption, *lysses*, on each side of the tongue. This has not been noticed in the dog; it is possible that it may be there, but no one has cared to examine the mouth to find out.

A canine brought into the presence of a rabid dog, or any other rabid animal, for that matter, often causes great fury in the afflicted one, and he will act as though he would like to attack the healthy creature.

As the disease progresses the animal loses the power of recognizing even friends, the pupils are dilated, and he will snap at any object easily within his reach; later, a general paralysis develops, and finally the victim dies of coma.

Owing to the varying manifestations of canine rabies it has been divided into two forms, furious rabies, and dumb rabies. The former has just been described, the animal being violent and showing a disposition to roam and do mischief.

In dumb rabies the animal does not have the furious stage, but it is dull and presents symptoms of coma throughout the course of the disease.

Rabies being a nervous disorder, it is highly probable that whether it assumes the furious or the dumb form, depends upon the presence or absence of exciting influences at the outset of the attack.

Dumb rabies is very much less dangerous than furious rabies, and fortunately is much the most frequently met with, the stricken animal dying without having done any damage; if this were not the case, loss of human life from an outbreak of canine rabies would be at least from four to six times greater than it is.

Williams describes the bark of a mad dog as unnatural, spasmodic, and husky, and more of a prolonged howl than a bark.

Symptoms of Rabies in other Animals.—The symptoms of rabies in other animals than the dog, are loss of or depraved appetite, prostration, restlessness, excitability, muscular tremblings, flow of saliva from the mouth, morbid sexual desire (especially in the bull), difficulty in swallowing, hallucinations, and painful sensations at the seat of the wound, shown by a disposition to rest the part or tear it with the teeth. There is a tendency to be violent and attack man and other animals, followed by exhaustion, paralysis, and death. A few years ago, in a certain deer park, in England, the deer were almost exterminated by an outbreak of rabies; those having been bitten by the dog in time became violent and attacked and bit their fellows, and as these became rabid they attacked others, until nearly the whole herd died.

Treatment.—The treatment of rabies is useless. A rabid dog should be killed as soon as the disease is recognized. If a dog is acting suspiciously he should be confined for a few days until it can be ascertained whether he is rabid or not. Dogs bitten by another known to be rabid should be shot, other animals should be isolated and kept under careful observation.

In outbreaks of rabies, if dogs are to be muzzled it should be general and not local, and should cover a period of from sixty to ninety days, a muzzling order in

one town and none in the adjoining township is of but little value, as a dog with furious rabies may run as far as forty miles, biting people and animals in his path; therefore, a muzzling order should at least include one or more counties, or better still a State. Furthermore, if it becomes necessary to adopt a muzzling order in case of an outbreak of rabies, it should be rigidly enforced, and every dog at large without a muzzle should be instantly shot.

In the treatment of bites inflicted upon persons by dogs believed to be rabid, there is probably little value in the customary cauterization; the better way is to have someone with an unabraded buccal mucous membrane suck the wound thoroughly, expectorating whatever can be drawn from it by this process, after which the injury should be dressed antiseptically.

Fortunately for the world, Pasteur's researches in rabies have now furnished an almost sure prophylaxis in the treatment of persons, or if necessary, animals, that have been bitten by a rabid dog, and a person having been bitten by a dog believed, or known, to be rabid should be at once sent to the Pasteur Institute in New York City, to undergo the preventive inoculation for this dangerous disorder.

Pasteur's preventive inoculation for rabies is based upon the fact that the medulla and cord of a rabid animal, hung in a glass jar for ten days, loses its virulency, the atmosphere in the jar being kept dry by means of a little caustic potash in the bottom, the virus-containing tissue being suspended in the jar by means of a thread, the orifice at the top being stoppered by means of a plug of sterilized absorbent cotton. Pasteur found that if an animal (he used apes for a while, owing to their resemblance to mankind) was inoculated first with an emulsion from a harmless cord, it could the next day receive an inoculation from one nine days old, then from one eight days old, and so on, until finally the fresh cord from an animal just dead from rabies could be used without injury to the inoculated animal, showing that the process granted immunity from the disease. He also found that an animal inoculated with the fresh cord could also be protected by means of the protective inoculation before the active virus could produce its effects. This same principle applies to persons bitten by rabid animals, and the loss of human life from dog bites among people thus protected is but a fraction of one per cent., the failures being due to the person to be inoculated arriving after too long a time has elapsed after being bitten by the rabid dog, or to the bites being numerous upon the face and neck, the rabid virus producing its effects before the protective inoculation has time to act. The death-rate from the bites of rabid dogs among persons not receiving the protective inoculation is said to be about sixteen per cent.

Scientists experimenting with rabies, or physicians or veterinarians in danger of receiving wounds from rabid animals, can undergo the protective inoculation, and then be bitten with impunity.

This treatment could also be applied to very valuable dogs, before or after being bitten, if the owner desired it.

Dr. H. C. Ernst, of the Harvard Medical School, has successfully demonstrated upon rabbits the correctness of Pasteur's work. Rabbits are now used in the Pasteur Institute for keeping up the supply of the virus of rabies, because they acquire the disease readily and are convenient to use, being easily handled and economical to breed and feed. The disease is communicated to them by means of trephining and introducing the virus under the dura mater.

Dr. Paul Gibier, director of the Pasteur Institute of New York, in his second annual report, April, 1892, gives the number of persons receiving the protective inoculation from its opening, February 18, 1890, to February 18, 1892, as 298; of this number 28 came from Massachusetts, undoubtedly making the death-rate in that State from this disease for 1890, 1891, and 1892, slightly smaller than it otherwise would have been.

Another point of interest as showing the subsidence of an outbreak in a certain community, is that from February 18, 1891, to February 18, 1892, twelve persons came from Massachusetts for treatment; while from April 1, 1892, to November 30, 1892, but three persons came from the same State.

Of the two hundred and ninety-eight persons treated at the Pasteur Institute of New York, during the first two years of its existence, but three died of rabies, and all of these were severely bitten, one, a child, in nineteen places, the other two men upon the right hand, wrist, or forearm.

No one should be allowed to run the risk of a terrible death from this disease, when in our own country there exists a place where he may receive treatment that is almost sure to save his life.

Another great mistake made in the management of rabies is the killing and destruction of the supposed-to-be-mad dog after he has bitten any one. The medulla and cord in the upper cervical region should always be carefully saved and forwarded to the Pasteur Institute, or some well-known bacteriologist, with which rabbits may be inoculated by trephining, in order to be sure of the correctness of the diagnosis; or if it is not practicable to remove the medulla and cord, the whole head may be cut off and forwarded by express. In hot weather the material should be packed in ice, so that decomposition will not set in in transit. Many a dog killed as mad is only suffering from some form of nervous excitement.

Post-mortem Appearances in Canine Rabies.—These are not well-marked, the most constant being a congestion of the membranes covering the brain and spinal cord. The only positive way of verifying the diagnosis is to test the medulla and cord, by means of inoculating some small animals, preferably rabbits. Two or three of these little animals should be tested, as a negative result in a single case is not enough to prove that rabies did not exist in the suspected dog.

Anthrax and Anthracoid Diseases.—Anthrax is the fifth and last of the diseases common to animals and man of sufficient importance to be considered at this time, although there are other maladies of minor significance that are by no means uninteresting.

Formerly a number of different diseases were all classified under the general name of anthrax, but now the term is applied only to that form known to be caused by the *bacillus anthracis*, and various other affections resembling anthrax in their symptoms, but due to another cause, are spoken of as anthracoid or as symptomatic anthrax.

Anthrax has been known since the earliest antiquity. It is undoubtedly spoken of in the ninth chapter of Exodus, in the eighth, ninth, and tenth verses: "And the Lord said unto Moses and unto Aaron, Take to you handfuls of ashes from the furnace, and let Moses sprinkle it toward the heaven in the sight of Pharaoh. And it shall become small dust in all the land of Egypt, and shall be a boil breaking forth with blains upon man, and upon beast, throughout all the land of Egypt. And they took ashes of the furnace and stood before Pharaoh, and Moses sprinkled it up toward heaven, and it became a boil, breaking forth with blains upon man and upon beast."

This is undoubtedly the first outbreak of anthrax upon record, possibly it may have been created for the occasion. When it is considered that the modern names of anthrax and charbon signify burning ashes, or a burnt coal, it seems somewhat remarkable that this name should have clung to it through the ages. Greek and Roman writers evidently describe the disease under various names in animals. When applied to man the former termed it anthrax and the latter carbunculus. In Arabian manuscripts of the middle ages it is found mentioned as *Atshac-al-Humrah*, or Persian Fire, all of these several terms evidently intended to convey some idea of the lesion. At least anthrax signifies a burning coal, while *charbon* is French, meaning black, from the dark-colored condition of the blood and organs engorged with it.

The Germans speak of the malady as *Milzbrand*, meaning inflammatory death of the spleen, as in anthrax the

spleen has always been found to be enlarged, softened, and dark-colored.

Fleming, in his "Veterinary Sanitary Science and Police," speaking of the geographical distribution of anthrax, says: "This is one of the most diffused and interesting of all the diseases of the lower animals, affecting as it does not only those which are in a state of domestication, but destroying wild animals as well. It prevails over almost the entire globe, in high latitudes as well as at the equator. It at times decimates the reindeer herds of the Laplander, and is only too well known in the tropics and in temperate regions by its dangerous and nearly always disastrous results. The carefully tended ruminants of the most highly civilized countries suffer equally with the wandering herds and flocks of the nomadic Arab, and it is as much dreaded by the Finn and Lapp as it is by the Mexican, South American, or Australian colonist. It has been carefully described by travellers and others, as they have observed it, as affecting animals on every continent and in almost every country."

In Europe the papers that have been published in regard to the nature and characteristics of anthrax are innumerable, as it has been more observed and studied there than elsewhere, for various reasons. First: In France and Germany there is more learning, and there exists there also a greater spirit of scientific research than anywhere else. Second: It occurs with more or less constancy in certain districts in Europe. Third: The losses it occasions are larger there because of the greater value of animals in thickly populated countries; hence it has on this account attracted much attention.

To just what extent it occurs in the United States it is difficult to say, owing to lack of reliable information on the subject, but it undoubtedly occasionally attacks animals, although happily true anthrax seems to be very rare. Perhaps in time, as our knowledge on such subjects extends, and more careful observations are made, it may be heard of more often than it is now. It must, however, be very uncommon in certain sections of the country, New England for example, as a light sandy soil with a gravelly subsoil is unsuitable for the spreading of anthrax, as "the regions where it abounds are in countries in which there are extensive marshes, or where the subsoil is tenacious; thus it happens that there are districts notorious for the prevalence of anthracoid affections, such as the marshes of Sologne, Dombes, and Bresse, and certain parts of Germany, Hungary, and Poland; in Spain the disease is enzoötic in the semi-submerged valleys and the maritime coasts of Catalonia, as well as in the Romagna and other marshy districts of Italy; while it is even epizoötic in certain districts of Russia and Siberia, where sometimes, in order to suppress the ravages of the terrible "*Jaswa*," the aid of the military authorities has to be invoked, and bodies of soldiers sent to bury or burn the carcasses of infected animals which float in the canals and swamps" (Fleming). In fact it is known all over the world since all time, and, as was shown in the scriptural quotation, it was one of the plagues of Egypt.

Virgil eloquently depicted its deadliness and contagiousness when he wrote:

> "The skins are useless, nor the tainted flesh
> Can water cleanse, or raging fire subdue;
> Nor is it possible to shear the fleece,
> All saturated with disease and filthiness:
> Nor can the weaver touch the putrid web.
> But should a man attempt the odious garb,
> With burning pustules and disgusting sweat
> His limbs offend; and in no lengthened time
> The fire accursed consumes his poisoned frame."

"Anthrax figures largely in the histories of the early and middle ages as a devastating pestilence among animals, and through them to mankind, and old Anglo-Saxon manuscripts contain many fantastic recipes, charms, and incantations for the prevention or cure of the 'blacan blezene' (black blain) and the 'elf shot' creatures. From those times up to the present day it has attracted more and more attention" (Fleming).

In man anthrax is known as malignant pustule; it has also been called "wool sorters' disease," because wool sorters may become infected by handling wool from sheep that had the disorder; it has also been seen among men who handle hides, as a result of being infected by skins which have been taken from animals suffering with this malady. Among the domesticated animals anthrax is seen most frequently in cattle and sheep, less commonly in the horse, although it seems to have a predilection for different species of animals in different localities. For example, in South Africa "Horse Sickness," and in India "Loudiana Disease," are looked upon as forms of this malady in the horse, while in England and on the Continent it is more commonly observed in cattle and sheep.

Texas cattle fever was formerly supposed to be a form of anthrax, and fowl cholera was believed to be an anthrax of fowls, but these views are now known to be erroneous.

Symptoms of Anthrax.—Anthrax may be general, without local manifestation, or there may be local lesions consisting of an immense amount of diffuse swelling near the seat of inoculation, as is seen in malignant pustule in man; in animals the local lesions are not so often seen as the general form, although the disease may be localized, as in "glossanthrax," where the tongue and throat are enormously swollen.

Ordinarily, in an outbreak of anthrax in a herd of cattle, or flock of sheep, the first symptoms noticed are not at all well marked; it may be that attention is first called to the matter by finding one or more animals dead in the field that had not previously been observed to be sick; if the creatures are then watched, it may be that an animal feeding quietly may be seen to suddenly throw up its head, fall down, struggle violently, emit a little blood from the rectum, and possibly a little bloody froth from the nose, and in a few minutes die.

If noticed more carefully, in some instances the animals affected may appear to be dull and depressed, and may separate themselves from their companions, and if the temperatures of the herd be taken the animals about to be attacked may show a good deal of fever, the temperature reaching 107° F., or 108° F., before any other signs are noticed, with the exception, perhaps, of dulness.

In some outbreaks the animals may have the disease in a modified form; here the cattle may appear dull, with loss of appetite, slight rigors, and a high temperature.

In dealing with such an outbreak, the pasture, food, and drinking-water should be changed, and all animals with high temperatures should be isolated from the rest, and treated with hyposulphite of soda, chlorate of potash, and similar remedies.

Anthrax is not contagious from one animal to another, but is spread by spores set free after the death of the patient by decomposition. These spores are very tenacious of life, and it is said that they may live for years in the soil; it is also believed that earthworms may bring them to the surface of the ground from carcasses of buried animals; and it is also believed that the disease can be carried by flies from diseased or dead animals, afterward biting men or healthy animals. Animals that die of anthrax should, therefore, be cremated, or if this is not possible, they should be buried very deep and covered with quick-lime, to destroy the spores and keep the earthworms away from the remains. Bacilli may also be excreted in the urine and fæces, thus infecting the ground, and are also found in the bloody discharges of moribund animals. Prevention then should consist in changing the pasture and water, cremating the dead, and in bad outbreaks, or in districts habitually infested with anthrax, Pasteur's preventive inoculation should be resorted to.

The mode of death in anthrax is, as a rule, the result of the bacilli multiplying to such an extent in the blood as to rob it of its oxygen and cause death in this way; it may, as has been described in the symptoms, occur even in the space of a few minutes.

The post-mortem appearances of an animal dead from anthrax are: first, the carcass is soon enormously swollen, the skin is tense and crepitates when handled, due to the accumulation of gases in the subcutaneous connective tissue; the blood is dark, tawny, and non-coagulable; the spleen engorged, softened, easily broken down, full of

black, tarry blood (hence the term "splenic apoplexy," one of the names given to anthrax in cattle); the lungs engorged, liver softened, kidneys softened and congested. If the disease is of a local character, the parts involved are swollen and infiltrated with serum—rigor mortis not well marked, or absent. Cover-glass preparations from the blood, or spleen, show numbers of the bacillus anthracis, and sections from the lungs or kidneys show the capillaries to be gorged with bacilli. If the gross appearances of anthrax be present on autopsy, but the characteristic bacilli cannot be found with the microscope, the disease is anthracoid, but not true anthrax.

In making post-mortem examinations upon animals supposed to be dead of anthrax, it must be borne in mind that a very dangerous disease is being investigated, and the veterinarian must have an unbroken skin on his hands, or wear rubber gloves; and the same advice applies to his assistants.

There is a disease of young cattle known in England as "quarter ill," or "black quarter," and by the French as "*anthrax symptomatique*," or symptomatic anthrax, that has been confounded with anthrax. In this disease there is local swelling, usually of one hind quarter, the skin crepitates over the affected part, and the animal is lame; often the disease is very fatal, but in this affection no rods are found in the blood and the spleen is not affected, but the lesions are in the subcutaneous and intermuscular connective tissue; the germ is found to be a vibrio, and is found only in the connective tissue, and not in the blood as in anthrax. From the symptoms and from some of its gross appearances, this malady of young cattle may be more easily mistaken for true anthrax, perhaps, than any other form of disease.

Etiology of Anthrax.—The anthrax bacillus was the first of the contagious disease germs to be discovered, probably because it is the largest; and as the microscope was improved and the subject of bacteria became better understood, the others were described one after another, although most of them were not recognized until within the last ten or twelve years. The discovery of the anthrax bacillus dates back over forty years, when in August, 1850, Davaine, a French scientist, described, in connection with Rayer, a rod-like body which he had found in the blood of animals suffering with this disease; these bodies had no spontaneous movement, and their length was equal to about twice the diameter of a red blood-cell.

Some years afterward a German savant, Pollender, described very exactly the bacillus of anthrax, its length, thickness, and constant existence in this affection; he compared it to vibriones, and considered it as belonging to the vegetable kingdom; he demonstrated its resistance to acids and alkalies and to coloring by iodine. The discovery of Davaine constituted a simple statement, while the memoir of Pollender contained a more complete description of the bacillus of anthrax, and he considered it as the essential cause of the malady. A little time afterward, Brawell described the same bacillus as being connected with human anthrax (malignant pustule). Davaine undertook later a large number of experiments, recorded in the Transactions of the *Académie des Sciences*, 1864 to 1873. He has inoculated the blood of animals with anthrax into a series of animals of different species, and has shown that even with a drop of this fluid, when very dilute, it was possible to reproduce the disease.

Koch (1876) and Pasteur (1877) found that the bacilli could be artificially cultivated outside of the animal body; they discovered the spores, and obtained pure cultures with which they reproduced the disease in all its integrity.

It can therefore be said, with our present knowledge, that anthrax is a disease entirely bacterian, the better established as such the more it is studied; there is no more doubt as to the etiology of anthrax, and the part which the bacillus plays in its production, than there is that acari produce mange.

The bacilli of anthrax are rods from 5 to 20 μ long and from 1 to 1.25 μ wide, and threads made up of rods and cocci, and the rods may be spore-bearing. The spores are more dangerous than the bacilli themselves, as they are very retentive of life, and will keep for a long time ready to form new bacilli, when they find a suitable soil for their development.

The growth of the anthrax culture in nutrient gelatine is characteristic: at first, a white line appears along the needle track, from this filaments grow out in various directions, giving it the appearance of what has been compared to an inverted Christmas tree; as the culture grows older the gelatine liquefies and the growth settles to the bottom of the test-tube as a white flocculent mass. It also grows on the surface of agar-agar as a snow-white plaque. It grows on potato, forming in thirty-six to forty-eight hours a creamy growth with a yellowish tinge, having the odor of sour milk.

It is aërobic, dying if deprived of oxygen.

In some instances the bacilli are so numerous in the capillaries of the lungs and kidneys of an animal dead from anthrax, that under a low-power lens the blood-vessels have the appearance of having been injected.

Dissemination of Anthrax.—It has been stated that when carcasses of animals which have died of anthrax are buried under the soil, spore development may still go on, and Pasteur believed that the spores were taken up to the surface by earthworms, which left them in their castings, and that animals grazing over the ground acquired the disease from these spores. This has not, however, been borne out by experiment; at the same time there are pastures where anthrax always exists. Bacilli occur in large numbers in the blood and discharges from the nose and mouth of moribund animals, as well as in the urine and fæces; they find a nourishing soil in decaying animal and vegetable matter, and having free access to oxygen, form copious spores, so that grass is extensively contaminated. In warm and marshy districts the spore formation is still more active, and they may be carried by floods over adjacent meadows.

Modes of Infection.—The animal may be directly infected through wounds of the mouth caused by siliceous grasses, or by the wounds of insects (insects have also been believed to carry the disease from place to place); and the intestinal and pulmonary mucous membranes are also regarded as pathways of infection.

In man the mode of infection is by the inhalation of spores, and ingress by the pulmonary or intestinal mucous membrane, or by direct inoculation through a wound or abrasion. In malignant pustule of man the bacilli are found in the serum of the pustule, the sputum, urine, fæces, and sweat, and if the disease prove fatal, in the capillaries throughout the body.

Davaine first discovered the bacillus of anthrax in 1850; others also noticed them, but did not realize the significance of their presence in the blood of animals suffering from anthrax. It was not until 1863 that Davaine, having had his attention once more drawn to these organisms in the blood, by Pasteur's discovery of the butyric ferment, was led to examine whether the anthrax bacilli, if introduced into the blood of an animal, would play the part of a ferment; for, if this were the fact, it would explain the rapid infection of the blood in a creature which had received into its veins, accidentally or experimentally, a certain quantity of this ferment.

Inoculating sheep and rabbits with the blood of a diseased sheep a few hours after its death, he constantly found these organisms, which he named *bacteria*; though when inoculated from the blood of an infected animal while it yet appeared in health and before these rods were visible, no effect was produced.

"In the present state of science," wrote Davaine, at this time, "nobody would think of going beyond these corpuscles to seek for the agent of contagion." This agent is visible, palpable; it is an organized being endowed with life, which is developed and propagated like other living things. By its presence and multiplication in the blood it undoubtedly produces modifications in that fluid, after the manner of ferments, which speedily destroy the infected animal."

This was the first direct evidence that a contagious disease is produced by a microscopic organism, and the

discovery converted into a fact what was before only a hypothesis. Davaine's announcement (like all new discoveries) was not received without doubt and hesitation by some, and two experimentalists (MM. Jaillard and Deplat) were unsuccessful in arriving at the same results by experiment, and consequently sought to refute his conclusions. Paul Bert also opposed his views and corroborated those of Jaillard and Deplat; "I can," he said, "destroy the bacteria in a drop of blood by means of compressed oxygen, inoculate with it and reproduce the disease, and cause death without any appearance of bacteria; therefore they are neither the cause nor the necessary effect of splenic fever; it is due to a virus." And so the controversy went on.

At this time a young physician in Germany, Dr. Robert Koch, who has since become famous as the discoverer of the B. tuberculosis, and the comma bacillus of Asiatic cholera, began to study the anthrax bacilli, or bacteria, as they had been indifferently termed; though Cohn, another German investigator, was also at work defining their morphology. Koch traced the life-history of the bacillus anthracis, and showed how widely it was distributed throughout the blood and organs, especially the spleen, of animals which had died of anthrax; after many attempts he succeeded in raising, or "cultivating," the fungus artificially, and watching its development under the microscope; noting that the rods, like those of the butyric ferment, multiplied by division, growing into long, straight or twisted filaments, in which in the course of time, if air is allowed free access, very minute oval spores are seen; then the filaments swell and burst, and the spores are set free. He found that these spores, if introduced into the blood of an animal, or cultivated artificially, grow again into the characteristic bacilli, which eventually become the long filaments that again form spores. Such is the life cycle of this deadly microbe, which multiplies so rapidly that the spores have been seen to germinate in three or four hours; and rodents such as rabbits, guinea-pigs, or mice, when inoculated with blood from an animal dead of anthrax, or with the bacilli or spores from an artificial cultivation, perish in from twenty-four to forty-eight hours, or more rarely sixty hours at the outside. Pasteur did not know possibly of Koch's researches, which were published in 1876, neither probably did the other disputants in France; for it was in 1876 that Bert gave an adverse opinion to that of Davaine. However this may be, Pasteur determined to settle the question as to whether Davaine or his opponents were right; and he adopted in his investigations the methods which had led him to such splendid results in his previous studies. He resolved to isolate the organism from infected blood, cultivate it artificially, and then test its action upon animals; in this work he was assisted by M. Joubert, as his paralysis would not permit his doing it alone. He reported to the Académie des Sciences, in 1877, that the bacilli were the only agents in producing anthrax, giving the behavior of the organisms as already described.

But it was necessary to explain the discrepancy between the results obtained by himself and Davaine, and those of Jaillard and Deplat. These latter had killed rabbits with blood from a cow that had died of splenic fever, and their blood was so virulent as to kill others, and yet no bacilli could be found in it; while Bert maintained that he had destroyed the bacilli by compressed oxygen, and still the blood retained its virulence. Pasteur demonstrated that the animals killed by inoculation where no anthrax bacilli were found, died of septicæmia, the compressed oxygen killing the bacillus anthracis, but not injuring the septic germs; he also succeeded in cultivating the anthrax bacilli and the septic germs separately, and found he could produce either anthrax or septicæmia, as he chose.

Pasteur also ascertained, when studying splenic fever, that the organism which produces it is under a particular influence which prevents it developing everywhere, and limits it to certain media, which one would not think differed from other media in any appreciable manner.

Thus in the ox, sheep, rabbit, guinea-pig, and some other creatures, it is easily inoculable and terribly fatal; but the dog and pig have to be inoculated several times before they are infected, and even not then with certainty; while fowls are proof against the disease.

Pasteur found that the reason why fowls are proof against the disease was due to their high temperature; he learned in his experiments that the germ could not be artificially grown at a temperature exceeding 112° F. Although the temperature of fowls is 105° F. to 107° F., the bacilli would not germinate there, and he thought this was due to the fact that the bacilli could not get oxygen as easily in the blood of fowls as in an artificial culture medium. He tried lowering fowls' temperature by having them stand in cold water (at 77° F.) until their temperature was lowered to about 98° F., when he found that when inoculated they readily acquired anthrax. He also tried the experiment of wrapping a hen, thus affected with anthrax, up in cotton wool and putting her in an oven at 95° F.; she gradually rallied and in a few hours was well. Fowls killed after being rescued in this way showed no trace of the bacillus anthracis in their bodies.

Pasteur in his researches in fowl cholera, which was formerly thought to be an anthrax of fowls, found that he could attenuate the germ of this disease so that fowls inoculated with cultures of it would not acquire the disorder, and yet, after being treated in this way, were found to have immunity from the malady when exposed to it.

This led to his attempting to produce an attenuated virus of anthrax which would protect inoculated animals from the disease. In this he was successful, and every year thousands of horses, cattle, and sheep in the anthrax districts of France receive protective inoculation with virus from Pasteur's laboratory in Paris, resulting in the saving of millions of francs to the nation.

The mode of attenuating the anthrax virus is by cultivating it artificially at a temperature of 108° F. to 109° F., and at this temperature it produces no spores; at that temperature, therefore, and in contact with pure air, the cultivation of bacilli destitute of spores, and of diminished vitality, can be effected. But in a few weeks the crop perishes, and sown on fresh media, produces no results; and it was found that after cultivating at this high temperature for two, four, six, or eight days, the strength was modified in proportion to the duration of the exposure. Animals can thus be protectively inoculated and given the same immunity from the disease as though they had had it in a severe form and then recovered.

Pasteur announced the results of his efforts to produce an attenuated virus for anthrax to the Académie des Sciences, on February 28, 1881.

It has been found best to use two vaccines, the first very weak (the *première*) and the second stronger (the *deuxième*), after which the animal suffers no ill effects if inoculated with a virus of full strength; the protection thus conferred lasts for at least a year or more; at the end of this time, if necessary, the animals can be reinoculated. "The discovery of this power in the weakened microbe," says Fleming, "of a contagious disease, to protect an animal from the lethal action of the same kind of microbe when in full virulency, must be held to constitute the most important part of Pasteur's services to medical science and to mankind, inasmuch as its effects may be of the greatest magnitude, and far-reaching, when made applicable to the many contagious disorders—so deadly and so little under the control of man—which affect our own species and the lower animals." "The destructive microbe is transformed in the laboratory, by the skill of man, and at will, into a benign, life-preserving agent."

In an extensive outbreak of anthrax, not easily controlled by ordinary means, and where it is likely to recur for several seasons, Pasteur's methods are well worthy of a trial, and in this case an investigation and preparation of vaccine should be undertaken by the United States Bureau of Animal Industry, or the nearest State experimental station, if properly equipped for such work, as Pasteur's vaccines often prove too strong to use upon animals in a foreign country, where the disease has hitherto been but little known. *Austin Peters.*

VITAL STATISTICS. Vital statistics are statistics relating to the chief events of the life of a human being in so far as they are of interest or importance to the community in which he lives. They, therefore, include statistics of births, marriages, sickness, and death, and as, in order to utilize the information they furnish for the good of the community, it is necessary to ascertain their relation to the community itself, as a whole, population has also to be considered in any discussion of vital statistics, although it belongs more properly to what may be called economic statistics.

The utility of such statistics can hardly be questioned at the present day, when it is so easy to demonstrate the improvement in the sanitary condition of civilized peoples, and to show that the first steps leading toward this improvement were statistical investigations and comparisons showing the possibility of better things. This is only one of the many directions in which such statistics are of use. They serve as a necessary guide in estimating the military strength of a nation, its fecundity, the prospects of future prosperity or decline, besides determining many commercial risks, and furnishing the sole foundation of life insurance.

In order to be thoroughly trustworthy, statistics should be complete and accurate; complete, because unreported figures might possibly change, in important respects, deductions made correctly from the figures that are reported; and accurate, because inaccuracy, if demonstrated, invalidates conclusions even more than incompleteness.

Sources of Vital Statistics.—The two main sources of vital statistics are the *census*, which furnishes an enumeration of the population, with various other useful information, and *current reports*, official and unofficial, compulsory and voluntary, which serve to fill in the gaps between the census years, and also to supply a continuous record of the sanitary and social condition of peoples and individuals.

The Census. History.—It is probable that enumerations of the people were made from very early times. Indeed, it would seem essential to the continued existence of a fighting nation to know how many fighting men it could depend upon in war; for such knowledge might often turn the balance for prudence or aggressiveness. A count of the warriors alone would not fully serve the purpose of a warlike chief, for he must also know, if he is prudent, and great leaders of men are usually prudent, what the hindrances to war are besides the lack of braves. He must know how many women and children are to be looked after, especially married and marriageable women, for, although in a savage race the old and crippled might be left to their fate as useless impedimenta, the young women are the hope of the tribe, and must be cared for at all hazards. So that even a count for military purposes alone must be a count of almost the entire population.

One of the earliest recorded enumerations is the one mentioned in the Book of Numbers, when the Jews were found by Moses and Aaron to comprise six hundred and three thousand five hundred and fifty fighting men. A census is said to have been taken in China in 2042 B.C., and in Japan about 100 B.C., but the authority for these statements is rather misty. The census, as an organized institution of the state, seems to have originated in Greece and Rome at about the same time, viz., during the sixth century B.C., and to have been established to facilitate taxation. In Athens the constitution of Solon divided the people into four classes, according to the income from property they owned, and as the amount fluctuated they had to be registered frequently. In some of the Greek states the valuation was made yearly, in others every two or four years.

In Rome, the census was established by the constitution ascribed to Servius Tullius, and the word census has come down to us from that time. It originally meant the registering and rating of citizens for purposes of taxation, from *censere*, to tax or assess, ultimately perhaps from *centum*, a hundred, through a verb-form *centere*, to hundred, or number by hundreds. The Roman census, although carried out for taxing purposes, elicited a good deal of information of the kind that is collected by our modern censuses. It called for the name, age, sex, class, relationship to others of the same household, and the conjugal condition, slaves and freedmen being also counted. The census, at first in charge of special officers called *censors*, was afterward conducted by the emperors, being taken every five years until about a hundred years after Christ, when the inter-censal periods became longer, even extending to fifteen years, and the institution finally disappeared with the dissolution of the empire.

From this time on there were partial enumerations of different peoples, none of them, however, worthy to be called a census. The most notable, perhaps, was the one carried out under William the Conqueror in 1081, in order to ascertain the number of landed proprietors in the kingdom, and the amount of their property, *i.e.*, to find out what resources he could depend upon in time of war. The results of this investigation are embodied in the famous "Domesday Book."

The first nation in modern times to obtain vital statistics in a systematic way, was Sweden. Early in the sixteenth century the clergy began to keep registers of the burials and baptisms in their parishes, and in 1686 this practice was made compulsory throughout the kingdom. A registry was required of marriages, births, and deaths, of persons moving to and fro from the parishes, a list of inhabitants by houses and families, and a record of extraordinary accidents in each year.

The first nation, however, to take a census under government control, seems to have been Russia, where partial censuses were taken in 1700, 1704, 1705, and 1710, and a more careful one in 1718 under Peter the Great, followed by others at irregular intervals of about twenty years through the remainder of the century.

The honor of the first systematic government census belongs to Sweden. In 1746 a census was taken by means of schedules of questions distributed among the population. The returns were not complete until 1749, and were not published until 1762. Subsequent censuses were taken at intervals of one or three years until 1775, and since that time have been taken every five years.

In England, singularly enough, although she had many a census taken in her colonies, no census worthy the name was taken before the present century. Records of deaths were kept in 1592, during the plague, but soon fell into disuse. In 1603 it was ordered that records of burials and christenings be kept in London, and parish registers were kept in many country places. In 1790 Sir John Sinclair undertook a census of Scotland at his own expense. He sent around schedules of questions to clergymen and others, receiving altogether answers from about nine hundred sources. The work occupied him seven years, and was published in twenty-one volumes, containing a great mass of well-digested and valuable information. Attention being thus called to the subject, Parliament, on December 31, 1800, passed an act providing for a census of England and Wales the following spring, and every ten years thereafter. The first census of England, accordingly, was taken March 10, 1801, and a little later one was taken in Scotland. In Ireland the first census was taken in 1811. The Imperial census was first taken in 1871, and is now simultaneous throughout the empire, being in charge of local officials, and generally taken the first Monday in April.

In the other states of Europe, censuses are taken at various intervals, as follows: *Austria*, since 1851, every six years; *Belgium*, since 1856, every ten years; *Denmark*, every ten years; *France*, first taken in 1801 and 1806, under the great Emperor, then in 1821, and every fifth year since; *Greece*, very irregularly; *Italy*, since 1861, every ten years; *Norway*, since 1815, every ten years; *Prussia*, since 1834, every three years; *Russia*, since 1850, every ten years; *Spain*, since 1857, every three years; *Switzerland*, since 1860, every ten years.

In other parts of the world, censuses are taken very irregularly. They are recently beginning to pay more attention to this subject in the various states of Central

and South America, in order to be able to furnish information for intending immigrants, and to aid in improving commercial relations with foreign countries. In Chili the sixth general census was taken in 1885. In Buenos Ayres, censuses were taken in 1869 and 1881, and in the Province of Santa Fé, Argentine Republic, the first general census was taken in 1887.

In the United States a census became a political necessity as a basis for popular representation in the legislature, and the constitution of 1787 accordingly provided that an enumeration of the people should be made "within three years after the first meeting of the Congress of the United States." Under this provision a census was taken in 1790, the returns being all referred to August 1st of that year, and has been taken every tenth year since. In 1830 the date was changed to June 1st, and this has been the date of all subsequent enumerations.

In most of the States provision is made in the constitution for a census at regular intervals. In some a census is required and in others only permitted. As a rule, the State census is taken at intervals of ten years and halfway between the United States census years, so that the census intervals are only five years.

Objects of a Census.—The chief purpose of a census is to ascertain the true number of people in any community or nation. But so many other items of information are desirable for different uses, that it has become the practice to collect in this way a vast fund of information upon other subjects, and the mass has become so unwieldy and the labor required of the census enumerators so onerous, especially in this country, that it has been a matter of serious discussion whether the amount of information sought to be obtained ought not to be considerably curtailed. The object being the procuring of trustworthy statistics for the use of the sanitarian, the student, the Government, and the tradesman, no more should be attempted than can be completely and thoroughly carried out.

The requirements of a good census are that it should be complete and accurate, and, for the sake of accuracy, that it should be taken rapidly and simultaneously throughout the country. These objects are, by common consent, best secured by distributing schedules of questions in advance, to be filled out by the head of the household or other trustworthy person, and then collected in one day by the officers who have been detailed for the purpose. This is almost the universal method of taking a census, excepting in this country, where the enumerators visit each household and fill out the schedules themselves by asking questions of whoever may happen to be in when they call. The chief objection to the use of prior schedules has always been that they necessitated two visits to each house, and a proportionate amount of extra trouble, and that in rural districts, and especially in those parts of this country that are very thinly settled and where the distances are very great, it would be almost impossible to induce people to take this trouble for the scanty pay they receive from the Government. But this objection, however valid in some places, does not hold in large towns, or through the greater part of the Eastern and Middle States, where the country is already pretty well settled, and exception could be made of those sections where the system of prior schedules was impracticable. Moreover, the use of prior schedules would save a great deal of time to the enumerator, the questions, in most cases, being all answered by the day for collection, so that he could in most cases easily cover his entire district in one day, gathering up all the schedules that he had distributed; or if, here and there, he found one that through ignorance or inadvertence, had not been filled out at all, or was filled out improperly, it would probably not make him over a day late in making his returns; whereas, in the United States census of 1890, enumerators had to use two entire weeks in going through their districts, even in large cities, and even then, in individual cases, the enumeration could not be completed within the time allowed.

By taking the census simultaneously in one day, another source of error is avoided, viz., omissions and duplications of names. Under our present methods, especially in large cities, where there is constant immigration and emigration, and incessant moving within the town itself, many persons may change their residence from one district, before they have been counted, into a portion of another district where the enumerator has already finished his work. This would result in the omission of many names from the record, repair of the error being possible only when the citizen himself takes the trouble to complain of it. The reverse case, the duplication of a name, is not so likely to occur, for most persons will object to answering the census questions twice, while few will take the trouble to hunt up the enumerator for the purpose of answering them.

A census ought to be taken at least every ten years, and it would be better to have one taken every five years, in order to minimize, so far as possible, the disturbing effects of migration. A more frequent census than this would involve more expense than would be fairly compensated for by the greater accuracy of the information obtained; for if a good census were taken every five years, the statistics for the intervening years could be calculated with a fair degree of approximation to the truth.

What Data Should a Census Aim to Secure?—For the purposes of vital statistics, the most important data given by a census are those relating to the sex, age, residence, birth-place, nationality, occupation, and conjugal condition. Other data, however, are of use to the community, and are usually collected by the census officials. This question has been discussed at the various International Statistical Congresses that have been held since the first one in 1853, and by the Congress held in St. Petersburg in 1872, the following recommendations were made, viz., that a census should be taken at least once in ten years; that it should be taken in one day, and preferably at the end of the year, when families are most likely to be in their homes; that the following data should be taken as an indispensable minimum, viz., name, sex, age, relationship to the head of the family, conjugal condition (single, married, or widowed), occupation, birth-place, and infirmities (deaf, dumb, blind, insane, or crippled). Also, when practicable, the language, religion, residence, and the state of the children as regards education. Naturally, the more numerous the items of information obtained, the more opportunity is afforded the compilers to detect errors by systems of cross-checking.

The comprehensive character of the modern census has been a matter of very gradual growth. In the first English census of 1801, which was taken under the direction of Mr. Rickman, the assistant clerk of the House of Commons, the following data only were obtained, viz., the number of persons, sex, number of houses, families, and a rough general classification of occupations. Ages were not taken until 1821. The first census that could be called fairly complete was taken in 1851, under the superintendence of Dr. Wm. Farr. In addition to age, occupation, and birth-place, which had been taken in previous censuses, inquiry was made about relationship, conjugal condition, infirmities, religious establishment, and education. The recent census of 1891 covered about the same ground.

The latest United States census, that of 1890, was much more comprehensive, and the schedule of population and social statistics included the following inquiries: name. sex, race, age, residence, relationship, conjugal condition, birth-place, birth-place of parents, occupation, illiteracy, infirmities, whether veteran of civil war, number of years in United States, whether alien or naturalized, number of children living and dead, and questions regarding ownership of residence, mortgages, etc.

Imperfections of the Census.—Some of these have already been referred to, as the omission or duplication of names, but these can be mostly avoided by great care in selecting intelligent and trustworthy enumerators, and taking the census in a single day. For example, in England, the census is taken under the direction of the Registrar-General, who issues instructions to all the sub-registrars throughout the kingdom. These men are all permanent employees of the office, and therefore well known,

and presumably careful and thoroughly acquainted with what is expected of them. The selection of enumerators rests with them, and they naturally choose persons on whom they, in turn, feel that they can rely for conscientious work. Moreover, they are especially advised, when possible, to persuade clergymen, school-teachers, and others of equal intelligence, to act as enumerators. The census of 1891 was taken on Monday, April 6th, and was intended to include all persons who slept in each place where a schedule was left on the night of Sunday, April 5th, special means being adopted for the enumeration of vagrants and gypsies, and persons living on boats and in caravans, travelling shows, etc.

The only very important error in a census that is properly taken, is one that can never be entirely done away with. It is that of the inaccurate reports of age. Many people do not know their real age, others do not care to tell, and others give round numbers off-hand, without taking the trouble to ascertain the true age of those whose history they are reporting to the enumerator. It is, therefore, better to take the ages, as far as possible, by single years, that is, to insist on the exact age being given; but even then this form of error creeps in, as will be seen in the following table, giving the number of the white population of Massachusetts, according to the United States census of 1880, at the ages ending in 5 or 0, with the number for the year before and after in each case:

Age.	Males.	Females.	Age.	Males.	Females.
4	18,133	17,703	34	10,707	11,914
5	18,037	18,115	35	17,873	18,678
6	17,618	17,395	36	10,962	12,384
9	15,977	15,793	39	8,798	10,153
10	16,847	16,690	40	20,146	20,748
11	14.964	15,110	41	6,624	7,277
14	16,325	15,938	44	7,474	8,710
15	15,114	15,479	45	14,739	14,911
16	15,156	16,404	46	7,627	8,467
19	17,425	18,661	49	6,516	7,480
20	17,481	21,555	50	14,847	16,399
21	16,422	17,774	51	5,061	5,568
24	15,858	18,934	54	5,916	6,580
25	17,502	20,201	55	8,109	8,674
26	14,652	16,816	56	6,045	6,326
29	11,813	13,102	59	4,297	4,555
30	20,583	21,967	60	9,556	10,441
31	9,493	9,946	61	3,600	3,856

The contrast between the numbers for 30, 40, 50, and 60, and the numbers just before and just after them, is almost ludicrous, and, contrary to the general opinion, the men seem to be as inaccurate as the women. The discrepancy, although marked, is somewhat less in the years ending in 5, and it is therefore better to combine the population, or the deaths, by the years ending in 5, as 25–34, 35–44, etc., rather than by those ending in 0, so as to minimize this source of error.

The universal tendency of females to understate their ages is well illustrated by the following table showing the white population living at certain age-periods in Massachusetts, in 1870 and 1880.

Age.	1870.	1880.	Age.
5–14	142,852	184,786	15–24
15–24	150,208	153,711	25–34
25–34	127,407	122,728	35–44
35–44	99,060	91,018	45–54

The arrangement of these columns is such that the number for each age-period for 1870, is opposite the number for the age-period ten years older in 1880. It is the rule, even allowing for variations in the birth-rate and in immigration and emigration, that the number of the population decreases with each successive year. Now, the persons who were between five and fifteen years of age in 1870, were between fifteen and twenty-five in 1880, and the latter number should be less than the former, whereas it is more than forty thousand larger. From the table it would appear that the tendency to understate the age declined a good deal after the age of thirty-five or forty, and that this great excess of women between fifteen and twenty-five was due to the including in this total a large number of women who were really overt wenty-five years of age. Errors of this kind, however, are so constant, that allowance can be made for them, and the numbers can be corrected so as to permit just conclusions to be drawn.

A somewhat similar difficulty occurs in the ages of infants as given in the census. There are found to be more children reported to be two years old than there are one year old, on account of the tendency of parents to advance the age somewhat. Thus the following are the figures for New York City from the United States census of 1880.

POPULATION, JUNE 1, 1880.

Age.	Males.	Females.	Total.
Under 1 year.	15,738	15,385	31,123
1 year.	12,054	11,712	23,766
2 years.	14,796	14,686	29,482
3 years.	13,975	14,199	28,174
4 years.	14,029	13,753	27,782

At the other extreme of life, the deviation from the truth is probably still greater. There are really very few persons who live a hundred years. and yet every census furnishes a long list of those who claim to be centenarians. The United States census of 1880 reported 4,016 centenarians, of whom 955 were white sand 3,061 were colored; the great disproportion of the races showing conclusively the tendency of the ignorant to overstate their age; for the total number of whites is given as 43,402,970, and of colored as 6,752,813, and the mortality of whites as 14.74 per 1,000, and of colored as 17.28.

In the New York State census of 1875, on page 199, will be found a table showing the "ages, as they appear in the records of former censuses, of persons whose names could be found in those returns, who, at the census of 1875, were returned as one hundred years of age and upward." There are 48 of these persons, but the names of only 11 of them appear in every one of the previous censuses, the records of which were examined for them. These are given below.

Number in the table.	Census of 1860.	Census of 1865.	Census of 1870.	Census of 1875.
1	79	83	96	102
8	82	80	94	100
9	80	100	94	108
10	85	89	95	100
11	87	92	97	102
22	78	86	96	101
36	78	90	97	105
43	85	90	96	100
44	56	70	70	100
46	65	90	97	102
48	87	92	96	102

Of these, No. 11 would seem to be genuine, and Nos. 10, 43, and 48 are also, perhaps; but the others are evidently wild guesses.

The total number of persons who are ninety years of age and upward, or who claim to be, is so small in comparison with the rest of the population, that such errors are of no practical importance, and cannot seriously affect any conclusions drawn from the population as a whole.

Data Obtained from Current Reports.—In most countries, the census enumerators are not called upon to ascertain any facts relating to births, marriages, or deaths, because the system of registration is so perfect that an account of these events is kept from month to month, or

week to week, or even from day to day. In this country, where, outside of a few of the large towns and some States, the registration is very imperfect, an attempt is made by the superintendent of the census to obtain these facts during the enumeration of the population. These attempts have not hitherto been very successful.

Births.—The only way to obtain these reports with any show of accuracy is to make them compulsory. In European countries, where everybody is followed up by the police, and is expected constantly to announce his whereabouts and almost every movement to them, there is ample provision for the procurement of such details. Parents are obliged to report births to the registering officers, generally within eight days after birth, and a child that has not been so reported, and whose name cannot be found upon the public records, has a hard time of it as he grows up. He cannot go to school without presenting his certificate of birth, and in many countries is not allowed to marry. In fact, he seems to be treated almost as an outcast. The consequence of such severe measures is that births are very fully reported. And the result justifies the means, for occasion may arise at any time, in any country, when the proof of the age of a particular individual becomes a matter of the first importance, and no evidence from private sources can ever equal in value and authority the contemporary record of the birth registered in a public office.

It is not probable that the record of births is complete in any place in the United States. Providence, R. I., long had the enviable prominence of being a town where the birth record approached completeness. The reports were collected by house-to-house visitation, and for some years the number returned was believed to be nearly what it should be. But of late years the system has been found not to work so well, and a certain proportion of the births, how large it is impossible to say, is not obtained.

In England and this country, where the inquisitorial methods of the continental police would not be tolerated, the reports of births are required from physicians and midwives. In England, the sub-registrars are also expected to use every means in their power to obtain perfect and accurate returns, for which they are paid a shilling a name. The system seems to work well there, and it is estimated by the Registrar-General that not more than five per cent. escape registration.

In this country, wherever registration is attempted, it is expected that physicians and midwives will make these reports, and penalties are provided by the laws in case they neglect this duty. Physicians often criticise this law as unjust, and, it must be confessed, they do so with some reason, for the ordinary form of certificate of birth requires the report of many bits of information which are not a matter of personal knowledge with the physician, and which he must ascertain by inquiry. Moreover, he is put to a slight expense and some trouble in sending the reports by post, or in carrying them himself to the office of registration. On the other hand, he holds a license to practise medicine from the State, which, in a measure, protects him from unlawful competition. In return for this, is it too much for the State to ask of him that he should report to public authorities all the particulars which the State may require about the births and deaths which occur within his personal knowledge, these being matters which it is of prime importance for the State to know. And it is not enough for the purposes of the State that he should report simply the place and date of birth, with the sex of the child, for more minute details are required for proper identification, such as the full names of the parents, with their birth-place and age.

Even under the most favorable circumstances, a certain proportion of births will escape registration. Some will not be reported through ignorance of the law; this will be the case especially when a child is born without attendance of doctor or midwife. Some illegitimate children will not be reported out of shame on the part of the parent, and others in order not to draw the attention of the authorities to private establishments of a disreputable character. And some children will be born of wandering people, gypsies and vagrants, who are both ignorant and negligent of the law.

In New York City, from time to time, attempts have been made to enforce the provisions of the law relating to the non-reporting of births. The penalty is ten dollars, but it has very seldom been collected. The unreported births are ascertained by a comparison of the record of deaths of children only a few months old with the list of reported births, and every time that action has been taken in this direction by the public authorities, there has been a notable increase in the number of births reported for a few months, when they again fall off, and the physicians and midwives become as lax as before. It is estimated that there are about sixty thousand births annually in New York City, and as only about forty-five thousand are registered, there is a deficiency of twenty-five per cent.

Marriages.—The registration of marriages is not of so much interest to the statistician as to the community at large. It is of the highest importance that this, the most marked and fateful voluntary act of a human lifetime, should become a matter of public record. It is of importance in connection with questions of legitimacy, of inheritance, of kinship, and as an index of the general prosperity, and a public record is especially necessary as a means for the detection of bigamy, and the protection of the wife and mother.

In New York, where the laws are very lenient regarding marriage, in order to enable women to protect themselves from the evil results of association with rascally men, the registration is imperfect. How many, or what proportion, of marriages escape registration it is impossible to say. It is probable that it is much less than the proportion of unregistered births, for the marriage-rate is as high in New York City as in almost any large city in the world. But some clergymen are forgetful, others are ignorant of the law, and some of the clergy of the Catholic Church, while they preserve a record of every marriage in the parish register, do not report them to the public authorities, because they do not wish to recognize in any way that the ceremony, which to them is a sacrament, is a civil contract. That this view is wrong is shown by the fact that the Archbishop of New York always reports to the civil authorities, all marriages solemnized by him.

In Massachusetts, Connecticut, New Jersey, and some other States, a license must be taken out before marriage, in order to make it legal. This regulation renders the registration probably nearly complete, and in this country it appears to be the only method of accomplishing this end.

Deaths.—By far the most important for vital statistics of all the events publicly registered are the deaths. Sanitary legislation depends largely upon the death records for its impetus and necessary changes. A study of such records furnishes vast stores of information regarding the origin, character, and methods of control of disease, and most of the sanitary improvements which are so marked a feature of our civilization within the last fifty years are based upon them. In these improvements, England is generally considered to hold the leading place, and Dr. E. A. Parkes did not overstate the truth in saying, "The fact that in modern times the subject of hygiene generally, and State medicine in particular, has commenced to attract so much the public attention, is undoubtedly owing to the application of statistics to public health. It is impossible for any nation, or for any government to remain indifferent when, in figures which admit of no denial, the national amount of health and happiness, or disease and suffering, is determined. The establishment of the Registrar-General's office in 1838, and the commencement of the system of accurately recording births and deaths, will hereafter be found to be, as far as the happiness of the people is concerned, one of the most important events of our time. We owe a nation's gratitude especially to him to whose sagacity the chief fruits of the inquiry are due, to William Farr."

In a considerable number of the large cities of the

United States the registration of deaths is quite complete and accurate. This is especially the case in Boston, New York, Philadelphia, Baltimore, Cincinnati, Chicago, New Orleans, and San Francisco. In some States, also, a good beginning has been made toward the registration of deaths, notably in New Hampshire, Massachusetts, Connecticut, New York, New Jersey, and Minnesota. Throughout the greater part of the United States, however, the registration is very imperfect, and although State Boards of Health have been established in thirty-eight of the States of the Union, they are in many places not yet in efficient working order, and are only slowly educating the public to a rightful apprehension of their duties in the matter.

The only way to procure complete registration of deaths is to render it very difficult or impossible to bury the body of a deceased person without notifying the authorities. Other methods have been tried, but without success. The collection of deaths from the books of sextons or undertakers, from church registers, etc., is a very uncertain method, and the non-compulsory report to a public authority is also untrustworthy. On the continent of Europe, the police methods render the registration of deaths as complete as that of births or marriages. A public officer, a "Todtenbeschauer," or "Vérificateur de décès," visits every house of death, inquires into the cause and circumstances of the death, and issues a certificate of interment. In England, "a person present at the death or in attendance during the last illness of the deceased person, goes to or sends for the registrar of the district in which the death happens, gives the requisite information, and signs the register book." This was the law up to the Compulsory Act of 1874, which imposed the obligation of making the report of death upon the medical attendant. There seems to be some opposition in England to making this report without remuneration, but in this country, although some physicians strenuously object to reporting births without pay, they acquiesce willingly in the necessity of reporting deaths.

It is believed that the system in use in most of the large cities of the United States is as good a one as can be devised.

The physician who attends the person during the last illness fills out the certificate of death so far as he is able, and signs it with his name and address. Certain items of family history, of course, can only be given by relatives of the deceased person, and those items are written in by some member of the family, or by the undertaker. The certificates are furnished by the office where the records are kept, and most physicians keep a supply on hand, which can be replenished, when necessary, on application at the central office. In New York City this certificate, properly filled out, must be presented at the office of registration, and a permit for burial is issued in exchange for it, the original certificate being retained, numbered, indexed, and bound for future reference. Every dead body must be buried within four days after death, unless a special permit has been granted allowing it to be retained above ground for a longer time. No bridge or ferry can be crossed without the presentation of this permit, and as most of the cemeteries are outside of the city, each permit has two coupons, which are torn off by transportation companies on the way. On arrival at the cemetery the permit is taken up by the keeper before the funeral cortége is allowed to enter the grounds, and is returned by him to the local Board of Health of the town in which the cemetery is situated. The coupons torn off at the bridges and ferries are returned to the Board of Health issuing the permit. Thus the only methods of getting rid of a dead body without reporting it to the office of registration and procuring a regular permit are: 1, To bury it in the cellar or yard of a house; an act almost sure to be seen and reported to the police; or 2, to throw it into the river, also exposing oneself to detection by the police or a curious on-looker; or 3, burning in a furnace or stove, subject to the same risk; or 4, to bury it in a cemetery, with the collusion of the police and ferry-masters, at the ferry, and of the keeper of the cemetery. As it is very little trouble to procure the proper permit, none of the above methods of eluding registration are likely to be adopted excepting in criminal cases, when risk must be run. But such cases, in any event, constitute a small part of the total number of deaths, so that we are justified in assuming that the record of deaths is virtually complete, excepting that a small number of children who were born alive and died shortly after may be reported as still-births, although every precaution is taken to prevent such reports.

In order to make these reports of value statistically, they must be full and accurate. In order to secure accuracy, they should all be examined by a medical registrar, who is qualified to judge of the sufficiency of the cause of death as given in each certificate. The lack of sufficient information is, as a rule, not so much the result of ignorance, as of carelessness or thoughtlessness on the part of the physician. At least this is the case in New York City. This point was illustrated recently by a certificate giving the cause of death as "Hæmorrhage, Anæmia of the Brain," with no indication whatever of the source or cause of the hæmorrhage. The certificate being returned with a request for further information, it was learned that the patient had suffered from a cancer of the neck for about three years, and the hæmorrhage was due to the erosion of large blood-vessels. In all such cases, a note to the physician usually brings out the information necessary to make the record complete, but if it does not, the certificate is sent to the coroner, who makes a special investigation of the case. This disposition of cases that are in any way suspicious is provided for by the following law: "Hereafter, when in the City and County of New York, any person shall die from criminal violence, or by a casualty, or suddenly, when in apparent health, or when unattended by a physician, or in prison, or in any suspicious or unusual manner, the coroner shall subpœna a properly qualified physician, who shall view the body of such deceased person externally, or make an autopsy thereon, as may be required (preparatory to an inquest)." Laws of 1882, Chap. 410, Section 1173.

There are some causes of death which, although at one time generally recognized as diseases by themselves, are now looked upon as symptoms merely, and should not be accepted upon a certificate. Probably the most common of these, and the one that shows the greatest tendency to persistence is *dropsy*. In New York City this has not been accepted as a sufficient cause of death since 1870, and the effect upon the death records of the rejection of all such certificates is very plainly shown in the following table:

Year.	Causes of Death.		
	Dropsy.	Heart disease.	Bright's disease and nephritis.
1868.....	177	615	594
1869.....	250	686	637
1870.....	116	699	890
1871.....	9	813	1,080
1872.....	9	894	1,040

The few cases of dropsy that will be found in subsequent reports are on certificates issued by coroners, which have to be accepted whether fully satisfactory or not.

The word *tumor* is another stumbling-block. This also is not accepted as a cause of death, excepting in the rare cases where no diagnosis has been possible, and an autopsy is refused. And even then the certificate is usually accompanied by a written explanation of the case from the physician, which is attached to and bound with it, so that the record is complete for legal purposes, although somewhat defective for the purposes of statistics.

The greatest latitude, however, has to be allowed in the reports of deaths of infants. The various ultimate causes of poor nutrition are so difficult to detect, when no subjective symptoms can be obtained, that a large proportion of infant deaths are returned under the rather

indefinite titles of marasmus, atrophy, debility, inanition, etc., and at present there seems to be no likelihood of any improvement in this direction. This difficulty is felt in other countries than this quite as keenly as here, as the following table shows :

Place.	Year.	Cause of death.	Number.	Total deaths.	Percentage of total.
Berlin.....	1888	Lebensschwäche.	1,723	29,294	5.88
London ...	1888	Debility, atrophy, inanition.	2,555	79,099	3.23
Paris.....	1891	Débilité congénitale.	1,371	52,262	2.62
New York.	1891	Marasmus, atrophy, inanition.	1,530	43,659	3.50

Besides these indefinite causes of death, some diseases require to be very fully reported on account of the possibility of criminality. The most prominent of these is peritonitis, which may result from criminal abortion, or from criminal assault. These chances render it necessary that every case of death from peritonitis should have the cause, if known, and the character of the disease (whether simple, puerperal, traumatic, tubercular, septic, etc.) stated upon the certificate. A few causes of death, the medical attendant feels obliged to slur over, or express in what to the friends are unintelligible or ambiguous terms, in order to avoid shame or offence to the survivors. For this reason, which is especially applicable to deaths from alcoholism and syphilis, it is very desirable to have the certificate of death entirely filled out by the family, with the exception of the medical certificate, before it goes to the physician. In New York many doctors use euphemisms, which are well understood at the permit office, but not understood by the family, such as temulentia for alcoholism, and lues, or specific disease, for syphilis. As a rule, certificates are honestly and conscientiously made out.

In England a certain proportion of deaths are uncertified as to cause, owing mainly to the fact that a report of death is often made by the laity, and a permit for burial issued in return. Thus cases which have died unattended by a physician may be reported as "wasting sickness," "sudden death," "visitation of God," etc. Even in London, about one per cent. of the deaths are uncertified as to cause. In New York, this cannot happen, for all such cases are referred to the coroner, every case being thus certified by a medical man ; infants who die within a few minutes after birth, when a midwife has been in attendance, being also referred to the coroner.

Of the total number of deaths in London, the coroner's or inquest cases constitute about seven per cent. (5,816 out of a total of 79,099 in 1888), while in New York they amount to about eleven per cent. (4,825 out of 43,659 in 1891).

It would be an excellent thing if the principal nations could agree upon a common nomenclature of diseases, so that it would be practicable to compare the statistics of one nation with those of another, with some degree of certainty that a comparison is being made between precisely similar things. This can, of course, be done even now, with some well-known and well-defined diseases, like small-pox, scarlet fever, and measles, and yet even here there are differences in methods which make it necessary to be very cautious. One must make sure whether the title small-pox includes or excludes varioloid and varicella, whether scarlet fever includes or excludes scarlatino-diphtheria, and whether measles includes or excludes German measles or Rötheln.

Another difficulty in the classification of diseases arises from the tendency of physicians to multiply causes of death in their reports. Often three or four causes of death are given, any one of which might have been fatal, with no indication on the part of the doctor as to which he considered to be the main factor in bringing about the death of the patient. A certificate, for example, giving as the cause of death, "cirrhosis of the liver, mitral insufficiency, chronic interstitial nephritis, hæmatemesis," throws a responsibility upon the registrar which the physician who attended the patient should take upon himself, viz., that of deciding under what heading the death ought to be classified. An attempt has been made, with some success, in New York, to obviate this difficulty by providing spaces upon the blank certificate for reporting the "chief cause" and the "complicating cause." This is not altogether satisfactory, for one physician might write down perforating ulcer as the chief cause and typhoid fever as the complicating cause, while another would more correctly report the ulcer as the complicating, and the fever as the chief, cause, and yet the ulcer was the real cause of death, being a fatal complication, while without the perforation the patient might have recovered. Better headings would probably be "Disease causing death," and "complications." These could hardly be misunderstood.

Still-births.—These should be reported, but by themselves and not as either births or deaths. The whole question of their proper position in statistics depends upon the question of what constitutes a birth ; for, of course, a human being, in order to die, must have been born. What then constitutes a birth ? A birth is the beginning of existence as an independent individual, as distinguished from one who is dependent for existence from moment to moment on the life of another individual. Now, the great change in the circulation of the child begins with the first breath, and whether the umbilical connection with the mother is severed or not, the circulatory connection will presently cease. The rule, therefore, should be never to report a child as still-born after it has breathed, if even only once. And it does not seem that any other dividing line than this can be found. "God breathed into his nostrils the breath of life, and man became a living soul."

The reports of still-births being largely made by midwives, most of whom are ignorant of everything exceptng the mechanical part of their business, they have to be scrutinized very closely in order to detect any indications of malpractice, and cases of live-born children returned as still-born because they have lived so short a time.

The registration of still-births, or at least the certification of them by a responsible person, is of great social and legal importance. Although they are not registered in England, they are required, under the new Registration Act, to be reported by the physician or midwife before burial. In New York City the certificates of still-births are arranged alphabetically and bound like the deaths. The proportion of still-births to the total number of births in England is estimated to be about four per cent. In France, under the provisions of the Code Napoléon, children who die before registration are counted among the still-born. It is estimated by Dr. Bertillon that twenty-two in one hundred of the children recorded as still-born breathed, and the percentage of actually still-born children, allowing for this correction, is about 3.6. In Belgium it is about the same. In New York City the number of still-births for 1891, as reported, was three thousand four hundred and fourteen, and of these two thousand five hundred and eight were seven months old or more and, therefore, viable children, and suitable for comparison with the statistics of other countries. As the birth-rate of France is very low, while ours is naturally high, a comparison with England is more appropriate, and if we take four per cent. as the proportion of still-births to births in New York City, we shall have about sixty-two thousand births a year, the same result arrived at in another way.

Reports of Contagious Diseases.—Probably no requirement which the law makes of physicians has met with more virulent opposition than the compulsory notification of cases of contagious disease. Many physicians object to it, not only as involving considerable trouble and expense, but as tending to bring them into conflict with the families of their patients, who look upon the report to the public authorities as a breach of confidence on the part of the physician, and who object strenuously to the visits of the sanitary inspectors. And yet it

is not difficult to see that such notification is necessary for the protection of the public. It is not only necessary in order that proper precautions may be taken by the relatives of the sick person, but that other persons living in the vicinity may also take their own precautions against infection. It has been found by experience that this notification must be given by the medical attendant. If it be left to the parent or householder, it will not be done at all, or will be done too late to be of service. The information should be given as soon after the diagnosis is made as possible, and in New York postal cards, specially printed in blank, are furnished by the Health Department for this purpose. The diseases required to be reported are small-pox, measles, scarlet fever, diphtheria, typhoid fever, yellow fever, typhus fever, and relapsing fever, also "any disease of a contagious or infectious nature;" and the report must be made within twenty-four hours after first visiting the case.

The information thus obtained is of use in various ways:

1. It enables the public authorities to combat epidemics at the very beginning, which is one-half of the fight. Abundant evidence can be adduced to prove that the spread of contagious and infectious diseases can be largely controlled by proper measures if all the cases are promptly reported.

2. It leads to the inspection of premises, and to the detection of unsanitary conditions which might otherwise have long escaped notice.

3. It educates the public to the idea that sanitary measures are effective, and so prepares the way for new legislation when needed.

4. In connection with other prophylactic measures, it enables the authorities to control the school attendance of children who have been exposed to infection.

5. It furnishes a large mass of material, larger than would be accessible to any single individual without such notification, from which the mortality of these diseases can be established, and the history and intensity of different epidemics compared, as well as their virulence as affected by locality.

There is no doubt that many cases go unreported on account of the objections of the parents, and these are more likely to be the cases that recover, for, as there is a severe penalty for not reporting, which, if the patient dies, can only be escaped by taking the risk of making a false statement of the cause of death, most fatal cases are reported before death, and thus mortality-rates made out by a comparison of the deaths with the number of cases reported are invariably too high. Many mild cases, too, are undoubtedly not detected, and if not followed by others, of course remain unknown. This is made certain by the frequency with which severe cases follow mild ones that have already recovered, and the true nature of whose illness is recognized for the first time when the subsequent cases develop.

Population.—The reports that have been mentioned are all that can usually be procured in England and the United States under the forms of law. On the continent the same stringent methods are used to preserve a running account of the population. Besides the census, taken at varying intervals, an account is kept daily of all persons entering or leaving a town, and this, with the accurate record of births and deaths, enables the authorities of each town to form a very close estimate at any time of the number of people it contains.

Voluntary Reports.—Various attempts have been made, at different times and in different countries, to procure statistics of sickness by voluntary reports from physicians. Many valuable statistical results have thus been obtained, partly by medical associations, partly by individual physicians, who distribute lists of questions to members of the profession, and partly by public officers. The most comprehensive and important reports of this kind, probably, are those compiled in Michigan, where the indefatigable secretary of the State Board of Health, Dr. Henry B. Baker, makes up weekly, monthly, and annual summaries of reports of prevalent diseases from different parts of the State. The system was instituted in 1876, and the reports include a great variety of diseases in addition to the infectious ones, which are most commonly the ones reported to the authorities. From these reports, carefully studied, Dr. Baker has been able to construct a theory of the causation of pneumonia, which has attracted by its ingenuity and plausibility the attention of the civilized world.

Such statistics must always rest under the imputation of being defective, unless the reports are made compulsory, and even then are very carefully looked after. But imperfect as they are, and probably always will be, they unquestionably afford valuable data, which can be used with advantage by one who is familiar with the deep pits of statistical fallacy and knows how to avoid them. A description of the methods in use in Michigan will be found in the article on "Registration of Disease" by Dr. Baker, in Vol. VI. of this work.

Methods of Using Vital Statistics.—I. *Population.* For the purpose of calculating birth, marriage, and death rates, the population is usually taken to be that in the middle of the year, *i.e.*, July 1st. As the census is generally taken on some other date, in the belief that the true number can thus be ascertained with greater accuracy, it becomes necessary, as a rule, to estimate the population for the middle of the year, *i.e.*, the mean population for the year. Thus in Germany the census is taken toward the end of December, in England on the first Monday in April, and in the United States on the first of June. All the numbers thus obtained have to be recast, in order to get the mean for the year.

Moreover, as the statistical reports are made up year by year, the population has to be estimated for the years intervening between two censuses, in some cases an interval of three years, in others of five, and in most of ten years. There are several ways of arriving at such estimates.

1. The total increase of population between the two censuses may be divided by the number of intervening years, and the quotient used as the annual increase, as expressed by the formula: $\frac{P' - P}{n} = R$, where P = population at one census, P' the population at a subsequent census, n the number of years between the censuses, and R the annual increase of population.

This method, however, is very faulty, because it assumes that the population increases by arithmetical progression, which could occur only in case the births exceeded the deaths by the same number every year, and there was no immigration or emigration, or else that the excess of immigration was precisely the same in each year—not the ratio of excess, but the numerical excess. These conditions could not occur, excepting as mere coincidences.

2. By keeping a record, or taking a yearly census, of the number of inhabited dwellings, and multiplying it by the average number of tenants to a dwelling as determined by the latest census. This method often gives excellent results, and is especially valuable for the correction of estimates procured in other ways. Of course, any decided change in the methods of building would make the method uncertain. In New York City, for instance, the tendency of late years has been very decidedly toward the building of large tenements and apartment houses and monstrous hotels, and the average number of tenants to a dwelling, as returned by the United States census, has steadily increased from 14.72 in 1870, to 16.37 in 1880, and 18.52 in 1890, while in London the number of persons to a house was 7.8 in 1861, 7.8 in 1871, and 7.9 in 1881, showing a remarkably even distribution of the population.

This method has been used with great success by Dr. James B. Russell, the widely known medical officer of health for Glasgow. The average number of persons per house, exclusive of the number in institutions and on the shipping in the river, was 4.738 in 1881 and 4.727 in 1891. Including the shipping population of 1881, the multiplier 4.738 was raised to 4.745. Multiplying the number of houses on the assessment roll of the City As-

sessor, he estimated the total population in the middle of 1891 as 574,800. The population, estimated according to the method of the Registrar-General, as described below, was 532,282. The population estimated on the basis of the census of 1891, which was taken in April, was 567,143, so that Dr. Russell's estimate was only 1.35 per cent. too large, while the Registrar-General's was 6.15 per cent. too small. Now, the number of persons on the shipping does not tend to increase very much, having been 639 in 1861, 569 in 1871, 590 in 1881, and 723 in 1891. Moreover, the discrepancy of about 1.5 per cent. between the census return of inhabited houses and the City Assessor's list of dwellings apparently represents the unoccupied dwellings. Dr. Russell therefore proposes, until the next census is taken in 1901, to use the following formula in estimating the population of Glasgow, viz.:

(Tenanted houses — 1% × 4.727) + Shipping + Institutions = Population,

and apparently this will give a very correct result.

3. The method in use in the office of the Registrar-General in London, based upon the assumption that the same rate of increase which existed during one inter-censal period, will hold good through a succeeding one. This is not by any means true, especially in a country like the United States, where immigration is so enormous in its proportions, and where there is such a constant shifting of population between different centres.

In order to estimate the population for the inter-censal years upon this assumption, the annual rate of increase has to be first ascertained in the following manner: The increase of a population by the excess of births over deaths, if the rates of both births and deaths to the population remain constant, is by geometrical progression, as the excess of births is annually increasing, owing to the continual introduction of newly married couples into the mass of the population. The problem, therefore, is the same as that of compound interest, and the annual rate of increase corresponds to the rate of interest upon a sum of money, and is obtained in a similar way. Thus, if p represents the population at one census, and p' the population at a subsequent census, n the number of years between the censuses, and r the annual rate of increase, then $1+r$ will equal the annual amount of each unit of population at the end of the year. That is to say, each unit at the beginning of the year will have become $1+r$ at the end of the year, just as one dollar at six per cent. becomes 1 + .06 or 1.06 at the end, and just as compound interest is calculated by multiplying 1.06 into itself for the required number of years, thus obtaining the final amount of principal and interest for one dollar, which is then multiplied by the whole sum to obtain the final amount; so $1 + r$ (whatever r may be), multiplied into itself for the entire inter-censal period, will give the entire rate of increase for each unit of the population, and this multiplied by the population of the first census will give the population of the second. To obtain the annual rate of increase, of course, this process must be reversed. The population of the second census must be divided by that of the first, giving the total rate of increase, or $(1+r)^n$; the root of the quotient thus obtained must be extracted, whose exponent is the number of inter-censal years. The formula then will read as follows:

$$\sqrt[n]{\frac{p'}{p}} = 1 + r, \text{ or } \frac{\log.\ p' - \log\ p}{n} = \log.\ (1 + r).$$

Having thus obtained the annual rate of increase, it is easy, by the use of logarithmic tables, to calculate the population for all the intervening years.

If the population has to be calculated for fractional parts of a year, the same method is used. Thus the United States census is taken as of the first of June, and the population must be estimated for the first of July. There are thirty days between the dates, and 365.24226 days in a year. The rate of increase has therefore to be calculated for $\frac{30}{365.24226}$ of a year. This can only be done by the aid of logarithms, the formula being—rate of increase for June $= \frac{365.24226}{30}\sqrt{1+r}$, *i.e.*, $\frac{\log.\ (1+r) \times 30}{365.24226}$.

This method is not altogether satisfactory, unless subject to correction. The census taken in 1891 in England brings out strikingly the imperfections of it. The following table shows the population for twenty-eight large towns of England estimated for the middle of 1891, by using the censuses of 1871 and 1881 as the base of calculation, with the population for 1891 estimated for the middle of the year from the censuses of 1881 and 1891, and in a third column the percentage of excess or deficiency in the first estimate as compared with the second.

	Population July 1, 1891, estimated from censuses of 1881 and 1871.	Population estimated from censuses of 1881 and 1891.	Percentage of excess or deficiency.
London	4,492,707	4,221,452	+ 6.43
Brighton	125,539	115,606	+ 8.59
Portsmouth	144 671	160,128	− 9.65
Norwich	96,202	101,316	− 5.05
Plymouth	79,339	84,464	− 6.07
Bristol	235,171	222,049	+ 5.91
Wolverhampton	84,277	82,799	+ 1.79
Birmingham	469,003	429,906	+ 9.09
Leicester	158,266	142,581	+ 11.00
Nottingham	252,217	212,662	+ 18.60
Derby	103,269	94,496	+ 9.28
Birkenhead	107,619	99,597	+ 8.05
Liverpool	620,443	517,116	+ 19.98
Bolton	117,034	115,253	+ 1.55
Manchester	506,325	506,469	− 0.028
Salford	251,024	198,717	+ 26.32
Oldham	151,158	132,010	+ 14.50
Blackburn	125,874	120,496	+ 4.46
Preston	106,141	107,864	− 1.62
Haddersfield	101,080	95,656	+ 5.67
Halifax	82,998	83,109	− 0.13
Bradford	246,101	216,938	+ 13.44
Leeds	370,261	369,099	+ 0.32
Sheffield	338,543	325,304	+ 4.07
Hull	219,812	200,934	+ 9.39
Sunderland	138,859	131,302	+ 5.76
Newcastle	165,016	187,502	− 11.99
Cardiff	121,477	130,283	− 6.76
Edinburgh	275,436	261,970	+ 5.14
Glasgow	532,282	567,143	− 6.15
Dublin	353,082	357,050	− 1.11

It will be observed that the tendency of this method has been to an excessive estimate of the population, ranging from an excess of only 0.13 per cent. up to 26.32, and that the extreme range in the estimates is between the latter percentage in excess and 11.99 deficiency. The excess of the estimated over the true population in London was 6½ per cent., amounting to more than a quarter of a million, while, on the other hand, the population of Manchester was estimated with extraordinary exactness, there being a difference of only one hundred and forty-four persons in a population of half a million. The table, however, abundantly shows the uncertainty of estimates made after this method, and the necessity of correcting them in some of the ways already mentioned. They afford also a powerful argument in favor of a more frequent census, for if sanitary measures are to depend in any degree upon death-rates, and the death-rate may vary twenty-five per cent. from the truth, the ground under our feet becomes very tremulous and unstable to build upon.

4. By adding to the population, as obtained by a census, the excess of births over deaths, and of immigration over emigration. In a community where one's information can be procured with a reasonable certainty that it is trustworthy, this is of all methods the best, for, of course, with perfectly accurate data, the correct number of inhabitants would be known directly, with a minimum of computation. In most countries this method cannot be used for lack of proper data, but it is very successfully carried out in Berlin, where the population is corrected week by week.

5. By a police census, which, as generally conducted

in this country, by personal visitation and inquiry, must of necessity be inaccurate and misleading. In the first place, it usually extends over several weeks, with no attempt to refer all information to a specific date, and, with so many ignorant and untrained men, will in many sections be slurred over in the most labor-saving manner possible. The census of a city or town might, however, be pretty well taken by the police, if use were made of prior schedules, the object and method of the census having previously been discussed in the newspapers. It would be very little trouble for every officer to leave in every house on his beat a sufficient number of schedules to supply the tenants, the schedules to be so carefully prepared as to indicate their purpose and the way they are to be filled out as to be understood by the dullest wits. These schedules being left on one day and gathered up on another, would give very little trouble to the police, and would at least serve as a valuable aid in correcting estimates of the population.

6. By a school census, in which the number of children of the school age is taken, and the total population estimated on the assumption that the proportion of such children to the total of all ages has remained the same as it had been found to be in the latest census.

Other methods to estimate the population are, by multiplying by a certain factor obtained by previous experience, the number of registered voters, or the number of names in the Directory. All of these methods are very faulty and give no result that can be depended upon, on account of the fluctuating character of the data. They can only be of any value as corroborative evidence of results that have been obtained by more accurate methods, or as correctives, if the tendency of them all is in the same direction, of results otherwise obtained, which appear upon their face to be inaccurate.

All of these methods, excepting those mentioned in 1 and 4, tend to an over-estimate of the true population, and thus to make the death-rate appear lower than it really is.

II. *Births.*—For the purpose of sanitary legislation the births are not as important as the deaths, but for commercial purposes, and especially in the solution of social and economical questions, it is very important to know accurately the true number of births in a community. For the purpose of making comparisons between one year and another, or between one country and another, or one town and another, with regard to relative fecundity, birth-rates are used, and these are obtained in various ways.

1. The usual birth-rate is the ratio which the births bear to 1,000 living of the total population. This is generally a little more than twice the marriage-rate, *e.g.* :

	Marriage-rate, *i.e.*, persons married to 1,000 living in 1888.	Birth-rate—births to 1,000 living in 1888.
England and Wales	14.2	30.6
Scotland	12.5	30.5
Ireland	8.4	22.9
Denmark	14.2	31.7
Norway	12 3	30.8
Austria	15.8	37.9
German Empire	15.7	36.7
Holland	13.8	33.7
Belgium	14.7	29.1
France	14.4	23.1
Spain	13.4	37.1
Italy	15.6	36.6

France, whose economists are so puzzled and apprehensive on account of her low birth-rate, is about the only exception to this general rule, that the birth-rate exceeds twice the marriage-rate. Applying this rule to New York City, where the marriage-rate for 1891 was 18.76 (although the reports of marriages are still known to be defective), the birth-rate should be nearly 38 per 1,000 ; or without reference to the population, the marriages reported having been 15,764 in number, *i.e.*, 31,528 persons married, the births should have been about 63,000, whereas only 46,904 were registered.

Throughout the United States, the registration of births is exceedingly imperfect, and even in the census year, when attempts are made to ascertain the true number, the authorities are always foiled. In the census of 1880 the enumerators furnished, so far as they were able to procure the information, the number of children living under one year of age, and the number reported as born and having died within the census year—which ought, leaving immigration out of account, to give the number born during the year. But the number obtained in this way is far too small, owing partly to the fact that not all were reported, and partly to the tendency of parents to call a child a year old when it is really only ten or eleven months. So the birth-rate of the United States was found to be only 31.4 in 1,000 living. For the different States the birth-rate varied from 19.1 in New Hampshire, to 41.9 in Utah, and 42.7 in Arkansas. From the total increase of population between 1870 and 1880, after eliminating some minor sources of error, Dr. Billings estimates the true birth-rate of the United States at 36 per 1,000.

The birth-rate is obtained by dividing the total number of births for the year by $\frac{1}{1000}$ of the population, or what is the same thing, multiplying the births by 1,000 and dividing by the population. It answers all practical purposes, but is not so accurate as the method immediately following, because it takes no account of the different age and sex distribution of the communities to be compared. It is evident, for example, that, with equal fecundity, there will be a higher birth-rate in a community of 10,000, with 4,000 married women of the child-bearing age, than in another of the same size with only 2,000 women of that age.

2. The birth-rate, as just indicated, may be estimated by comparing the number of births with the number of child-bearing women in the community, *i.e.*, of women between fifteen and forty-five years of age. Comparisons made between such rates are more satisfactory than those depending upon the first method.

The birth-rate is affected by various causes which tend to increase or diminish it in different years, and to make it greater or smaller in one country or one city than in another. Some of these causes may be mentioned here.

The influence of social condition is believed to be considerable, and it is the general opinion that the families in the well-to-do classes of the community are smaller than among the poor. There are very few data bearing upon this question, and it is always to be borne in mind that the upper classes are more prudent, as a rule, in regard to marriage, that marriage is entered upon later in life, and that as people improve their social condition their ages advance. Moreover, in the large cities of this country the poorest classes contain a large proportion of newly arrived foreigners, so that the race question is involved.

The statement is often made that the native American stock is gradually dying out, because the women are less fecund than the foreign-born women. Dr. Nathan Allen, of Massachusetts, maintained this with great vigor, and there seems to be small doubt that foreign-born women do, as a rule, have more children. This may, however, not be due to greater natural fecundity, or to the prevalent use of unlawful means to avoid pregnancy or end it abruptly on the part of American women, as has been urged in such a sensational manner by some physicians, but may be due to the recklessness with which they marry. To most foreigners, soon after their arrival in this country, the ease with which they obtain employment, and the high wages which, to them, must seem enormous, seem to lift a heavy burden from their hearts, and with the rebound, like that of a suddenly released spring, having no fear of the future before them, they rush precipitately into marriage. In New York City, marriages of young Italian and Russian girls of from fourteen to seventeen are very common, and beginning so early, their families are often large. Then, as shown by Dr. Edward Jarvis, a very distinguished statistician,

the greater mortality of the children of foreign parentage offsets their greater fecundity, so that the natural increase is at a lower rate in the foreign than in the American families.

The most recent statistics upon this point now accessible, are those in the city registrar's report of the city of Providence for 1891, from which it appears that in 1890 1,496 American mothers had an average of 3.17 children to a family, while 1,864 foreign-born mothers had 3.60 to each family; in 1891 the proportions respectively were 3.08 and 3.52. The total number of children born of American mothers in 1891 was 1,698, and the deaths of children under one year of age were 251, a ratio of 14.78 per cent. There were 2,178 births of foreign-born mothers, and 325 deaths of children under one year, a ratio of 14.92 per cent. The corresponding ratios for the thirty-six years from 1856 to 1891 inclusive, were 13.91 and 14.63. In New York City, in 1891, out of 38,689 children of unmixed parentage whose births were reported, 11,852, or 30.63 per cent., were of native parentage, and 26,837, or 69.37 per cent., of foreign parentage. The statistics of deaths by age and parentage are not published, but the deaths of children of unmixed parentage by marasmus, inanition, atrophy, etc., who were mostly children under one year of age, were 730 in all, of whom 270, or 36.98 per cent., were of native parentage, and 460, or 63.02 per cent., were of foreign parentage.

In the New York State census of 1875, some statistics were obtained that seem to be of especial value in relation to this point, for that census was exceptionally well taken, and in this respect particular care was exercised, as it was the first time such an inquiry had been made. Mr. Franklin B. Hough, the superintendent of the census, says (p. lxvii. of the Introduction): "In the present census an inquiry was first introduced having this object in view (viz., relative increase of population with women of American and foreign birth). The column was headed, 'Of how many children the parent?' The instructions gave the following instructions for reporting it: 'This inquiry is to be made only of adult *females*, and usually of wives or widows. It should, in all cases, include the number of living children the woman has borne, *whether now living or dead*, and *whether present or absent* from the family. These children may perhaps be themselves the heads of families and residents of another State, or they may have died in childhood. The object of the inquiry is to obtain data for determining the natural increase of the population in this State among the various classes, and it should be taken fully and uniformly to possess value. Be careful to note in this column the number of children borne by females now aged, as well as that of those now surrounded by their families. We can thus determine the relative rate of increase of a former age, for comparison with the present.'" These statistics were reported very uniformly, and quite as fully as could have been expected. The table on the next column shows the result:

Number of children born.	Nationality of women.		Total number of children.	
	American.	Foreign.	American mothers.	Foreign mothers.
0	74,366	40,886	0	0
1	82,279	42,038	82,279	42,038
2	79,346	44,573	158,692	89,146
3	65,904	42,420	197,712	127,260
4	54,099	37,827	216,396	151,308
5	42,581	30,870	212,905	154,350
6	33,015	25,356	198,090	152,136
7	25,242	18,160	176,694	127,120
8	20,024	13,502	160,192	108,016
9	15,164	9,677	136,476	87,093
10	11,288	6,991	112,880	69,910
11	7,259	4,069	79,849	44,759
12	4,995	2,772	59,940	33,264
13	2,431	1,440	31,603	18,720
14	1,303	912	18,242	12,768
15	512	391	7,680	5,865
16	246	214	3,936	3,424
17	89	73	1,513	1,241
18	42	49	756	882
19	31	28	589	532
20	14	19	280	380
21	7	10	147	210
22	7	7	154	154
23	1	6	23	138
24	2	0	48	0
25	3	2	75	50
Total.	520,250	322,312	1,857,151	1,230,774

These women, 842,562 in number, presumably all wives or widows, constituted 67 per cent., or about two-thirds, of all the females in the State above the ages of fifteen, the total being 1,250,220. Of the American-born women, 74,366, or 14.29 per cent., were childless, while of the foreign-born women only 40,886, or 12.68 per cent., had no children. If we take the total number of women in both classes, we find that the American women had an average of 3.57 children apiece, and the foreign-born women an average of 3.81 apiece; while if we leave the childless women out of the calculation, the American women had an average of 4.18 children, and the foreign-born an average of 4.38. Thus, as by the other data given, it seems that the fecundity of foreign-born women, as indicated by the number of children borne by each mother, is a little greater than the American, but by so small a margin that at any time the scales may turn the other way. In New York City, where the foreign-born population preponderates, the results, by the same census, were as follows: Total number of women about whom these statistics were obtained, 160,104; of these 44,084 were American, and 116,020 were foreign born; the American women had 122,344 children, or an average of 2.77, and the foreign-born women 351,840, an average of 3.03; or, excluding the childless women, who constituted 18.70 per cent. (8,247) of the native women, and 15.81 (18,346) of the foreign-born, the American women had an average of 3.41 children, and the foreign born an average of 3.60.

Now, this difference of fecundity is really very slight, in comparison with what has been assumed on rather insufficient data, and it is not at all improbable that it would disappear altogether if native women were in the habit of marrying at as early an age as the foreign, and lived under the same social conditions.

There is another potent cause of the higher birth-rate among the foreign-born population, that has been briefly referred to previously. It is the greater mortality among the infants of foreign mothers, partly, it would appear, for lack of acclimatization, and partly because they belong, as a rule, to the poorer classes, and live herded together under the most unsanitary conditions, surrounded by filth, neglectful of personal cleanliness, and eating insufficient and inappropriate food. A high rate of mortality among infants is always accompanied by a high birth-rate, on account of the shortening of the nursing period, and the consequent shorter intervals of child-bearing.

The birth-rate also varies with the race of the parents. In the United States the birth-rate among the colored people is much higher than among the whites, the rates, according to the census of 1880, being 32 for the white population, and 38.6 for the colored; or, for the whites 127.1 births for every 1,000 women between 15 and 49 years of age (the child-bearing period), and 163.8 for every 1,000 among the colored. Whether this is due to greater fertility of the colored race, or to earlier marriages and greater indifference to consequences, we have not the data to say, but the latter supposition is probably the true one.

The birth-rate is always higher in cities than in agricultural localities, and in industrial and mining districts than in those that are more sparsely populated. This is due to causes that have been already mentioned elsewhere, viz., early marriages, greater infant mortality, and also the greater proportion, as a rule, of women of the child-bearing ages.

The comparative fecundity of the mothers in different European states is shown in the following table, prepared by Dr. Farr:

Years.	States.	No. of births to a marriage.
1876	Italy,	5.15
1876	Prussia,	4.92
1876	Sweden,	4.84
1876	Holland,	4.83
1876	England,	4.63
1876	Belgium,	4.48
1870	Spain,	4.47
1876	Denmark,	4.24
1876	Austria,	3.73
1876	France,	3.42

The number of births to a marriage is estimated by Dr. Farr, by assuming that the interval between the mean age of marriage and the mean age of mothers, in England, is 6 years. In this way he estimates the number of births to a marriage, in 1874, by dividing the legitimate births for that year by the average number of marriages in the three years 1867–1869 = 4.57. In 1864 the proportional number was 4.30.

Proportion of Males to Females at Birth.—There is always an excess of male children at birth, more marked in some countries than in others, but giving an average result of about 104½ males to each 100 females. The following table is taken from Newsbolme's "Vital Statistics," p. 62, and shows the proportion of male to female births during the ten years, 1870 to 1879, in different European countries.

Country.	Males born to every 1,000 females born.
Italy	1,071
Austria	1,068
France	1,064
Switzerland	1,063
German Empire	1,062
Holland	1,061
Belgium	1,059
Scotland	1,057
Ireland	1,056
England and Wales	1,039

Illegitimacy.—The statistics of illegitimate births must always be somewhat defective, for in addition to the carelessness or ignorance which causes many mothers in wedlock to neglect to register the births of their children, or see that the professional attendant does so, there is the added reason of shame and consequent secrecy. In New York City almost all of the births that are reported as illegitimate occur in public institutions.

The most accurate method of stating the proportion of illegitimate births is to compare the number of such births with the total number of unmarried women of child-bearing ages. A comparison may also be made with the total number of births, or with the total number of the population, as so many per 1,000.

In England, in 1871, the illegitimate births were 5.6 per cent. of the total births registered. In London, the rate varies little, according to the Registrar-General, and is about 4 per cent., of the total births. In New York City, the illegitimate births in 1891, the first year for which an account of them was kept, numbered 1,104 out of 46,904 births, about 2.35 per cent. The following table, from Dr. Farr's thirty-ninth report, is suggestive as regards the causes of illegitimacy: it shows the relation between the illegitimate births and the proportional number of spinsters in different counties in England, the counties being arranged in groups in the order of the rate of illegitimacy.

Groups of counties.	Children born out of wedlock to every 100 births, 1876.	Proportion of spinsters aged 20–40 to every 100 women living at the same age in 1871.
1st group of ten	3.9	36.1
2d group of ten	4.6	37.9
3d group of ten	5.0	39.1
4th group of ten	5.9	38.5
5th group of six	8.0	41.3

Effect of Birth-rate on Age-constitution of Population.—When the birth-rate is high there will be an excess of young people in the community, and of course an excess of infants as compared with communities where the birth-rate is lower. As the mortality of infants is always high as compared with any portion of the community, excepting the very old, it has been maintained by some that a high birth-rate will always be accompanied by a high death-rate. That this is not the case has been conclusively shown by Dr. Farr and Mr. Noel A. Humphreys. This matter will be more fully dealt with hereafter.

III. *Marriages.*—The marriages are not of much importance to the vital statistician from a sanitary point of view, their interest relating chiefly to questions of social and political economy. The methods of estimating the marriage-rate most in use are two, viz.: as so many marriages per 1,000 of the population, and as so many persons married per 1,000; the latter rate being obviously twice as great as the former. Marriages may also be estimated as so many per 1,000 of adult males or of adult females, or as so many per 1,000 of adult unmarried males or females.

The marriage-rate is always higher in urban than in rural communities, partly on account of the practice of very early marriages among the poor, and partly because there is a greater proportion of young people of the marriageable age who are constantly migrating from the country into the towns in search of easier living.

The marriage-rate is considerably influenced by the national prosperity. As Dr. Farr puts it, the frequency of marriages depends largely upon the price of corn. A general tendency in this direction is shown by the following table, showing the marriage-rate and price of wheat in England for several periods of years.

Years.	Marriage-rate.	Price of wheat per quarter.
		s. d.
1838–40	15.6	72 6
1841–45	15.7	54 9
1846–50	16.5	51 11
1851–55	17.2	55 10
1856–60	16.7	53 5
1861–65	16.8	47 5
1866–70	16.4	54 7
1871–75	17.1	54 8
1876–80	15.3	47 6
1881–85	15.1	40 1

A more significant table, illustrating the way in which the marriage-rate is affected by crushing poverty and a wretched environment, is the following table, in which the marriage-rates of England, Scotland, and Ireland are contrasted for a series of years.

Year.	England.	Scotland.	Ireland.
1871	16.7	14.3	10.7
1872	17.4	15.1	10.0
1873	17.6	15.5	9.6
1874	17.0	15.3	9.2
1875	16.7	14.8	9.1
1876	16.5	15.0	9.9
1877	15.7	14.4	9.8
1878	15.2	13.4	9.5
1879	14.4	12.8	8.7
1880	14.9	13.2	7.8
1881	15.1	13.9	8.5
1882	15.5	14.1	8.5
1883	15.4	14.0	8.5
1884	15.0	13.5	9.1
1885	14.4	12.9	8.6
1886	14.1	12.4	8.4
1887	14.2	12.5	8.7
1888	14.2	12.5	8.4

The marriage-rate has been declining, as a rule, in all the civilized countries of the world during the past twenty years. In spite of the vaunted advance in civilization, as statistically shown by the increase of comforts and the growing cheapness of the necessities of life, the

struggle to get along seems somehow to be fiercer, and the effects are vividly shown in this single point. The following table shows the marriage-rates of various European countries since the war of 1866, at intervals of three years.

Countries.	1866.	1869.	1872.	1875.	1878.	1881.	1884.	1887.
Austria	13 0	20.7	18.6	17.1	15.2	16.0	15.7	15.6
Belgium	15.7	14.8	15.5	14.5	13.4	14.1	13.5	14.2
Denmark	16.8	14.7	15.0	17.0	14.8	15.6	15.6	14.0
England&Wales	17.5	15.9	17.4	16.7	15.2	15.1	15.0	14.2
France	16.0	16.5	19.5	16.4	15.1	15.0	15.3	14.5
German Empire	....	....	20.6	18.2	15.4	14.9	15.7	15.6
Holland	16.7	15.4	16 5	16.7	15.5	14.6	14.4	14.0
Hungary	....	....	....	....	18.7	20.0	20.5	17.9
Ireland	10.8	10.0	10.0	9.1	9.5	8.5	9.1	8.7
Italy	11.3	16.0	15.0	16.8	14.2	16.2	16.4	15.7
Norway	....	....	14.0	15.7	14.6	12.8	13.7	12.5
Prussia	15.6	17.9	20.6	18.0	15.7	15 2	16.1	16.0
Scotland	14.7	13.4	15.1	14 8	13.4	13.9	13.5	12.5
Sweden	13.4	11.3	13.9	14.0	12.9	12 4	13.1	12.5
Switzerland	....	14.4	15.7	17.9	14.7	13.6	13.8	14.2

The rates in 1872 are very high in the German Empire and in France, as usually happens after a devastating war, as if nature set herself to work immediately to repair the waste of life. The same phenomenon was noticed in this country after the civil war.

As to the ages of those who contract marriage, the following figures are given by Newsholme for England, corresponding figures for this country not being readily obtainable. Taking marriages and remarriages separately, the mean age of widowers married was 43.8 years; of widows, 40.1; of bachelors, 26.2; and of spinsters, 24.6 years. There has been in England a decided tendency of late years to postpone marriages, as the following table shows:

Year.	Age at marriage, in years.	
	Bachelors.	Spinsters
1880	25.8	24.4
1881	25.9	24.4
1882	25.9	24.4
1883	25.9	24.4
1884	26.0	24.5
1885	26.1	24.6
1886	26.2	24.6
1887	26.2	24.7

The marriage relation is entered into later in life by some classes than by others. Notably the professional men, who spend many years of struggle before they have an income sufficient to justify them in marrying, marry late in life, as shown by the following table, taken from the Registrar-General's report for 1886:

AVERAGE AGES AT MARRIAGE OF BACHELORS AND SPINSTERS IN OCCUPATIONAL GROUPS, 1884-1885:

Occupations.	Bachelors.	Spinsters.	Difference between ages.
Miners	24.06	22.46	1.60
Textile hands	24.38	23.43	0 95
Shoemakers, tailors	24.92	24.31	0.61
Artisans	25.35	23.70	1.65
Laborers	25.56	23 66	1.90
Commercial clerks	26.25	24 43	1.82
Shopkeepers	26.67	24.22	2.45
Farmers and sons	29.23	26.91	2.32
Professional and independent class.	31.22	26.40	4.82

It will be observed that the difference between the ages of husband and wife becomes greater as the age at marriage increases.

In New York City, in 1891, two-thirds of the grooms were under 30 years of age (10,663 out of 15,764), and two-thirds of the brides were under 25 (10,116 out of 15,764). About 3 per cent. of the grooms (460) were under 21 years of age, and 29 per cent. (4,609) of the brides; 431, or a little less than 3 per cent. of the grooms, were over 50 years of age, and only 119, or ¾ of 1 per cent. of the brides.

The following interesting note is made by Dr. Farr about English marriages: "Widowers are more inclined to marry than bachelors. At ages 35 to 40, to every bachelor who married in the three years, 1870–72, 4 widowers remarried; at ages 40 to 45, 5 widowers remarried to every bachelor who married. As age advances this disparity increases, and at ages 50 to 55, the relative proportions were 1 bachelor to 7 widowers; at 60 to 65, 1 bachelor to 8 widowers, and at 65 to 70 the same. These are marriages out of equal numbers."

As to the previous condition of those who marry, of course the great majority are bachelors and spinsters. In New York City, in 1891, they constituted 81 per cent. of the total. More widowers married spinsters than married widows, and more widows married bachelors than married widowers.

Still-births.—So little attention has been paid to still-births that very few statistics have been gathered relating to them. In England they are almost entirely ignored. In France they are mingled in a general hodge-podge with live-born children. And yet, for scientific interest and possible real importance, they certainly deserve more attention than they have received. I quote again from Dr. Farr (twenty-fifth annual report): "The age of man is reckoned from the date of birth, but before that date the fœtus has lived its intra-uterine life, and the instant in which the sperm-cell and germ-cell intermingle is the true time of the embryo's origin. Respecting the rate of embryonic mortality there is little definite information, but it is probable that, as the mortality in the first year of breathing life rapidly increases as we proceed backward from the twelfth to the third, second, and first month, the same law prevails during embryonic life, until we arrive at the destruction of an immense proportion of the spermatozoa and ova which are provided to secure the continuation of the species."

The still-births are probably reported with more accuracy and conscientiousness in the city of New York than in any other large city of the world, so far as can be judged from an examination of their mortality reports.

In the year 1891, 3,414 still-births were reported, being in the proportion of nearly 8 to every 1,000 deaths, and more than 5 to every 1,000 births. This great apparent excess of still-births in New York is due to the fact that the still-births, as reported elsewhere, include, as a rule, only the dead-born of fœtuses of a viable age, *i.e.*, of the seventh month of pregnancy and upward, while the figures for New York include abortions as early as the second month. In 1891, for instance, about 6 per cent. of the total number were earlier than the fifth month, 14 per cent. earlier than the sixth month, and over 26 per cent. earlier than the seventh month, while only 44 per cent. of those reported were born at full term, *e.g.*.

MONTH OF UTERO-GESTATION OF STILL-BIRTHS REPORTED IN NEW YORK CITY IN 1891.

1	2	3	4	5	6	7	8	9	10	Not stated.
..	7	69	142	264	422	487	507	1,508	6	2

More males than females are still-born. This is generally attributed to the fact that the male children, as a rule, have larger heads than the female, and thus parturition is rendered more difficult. The difference, however, is partly accounted for by the fact that, for some occult reason not yet found out, male births of any kind are in excess of the females. According to Newsholme, in the ten years 1865 to 1875, the male still-births were in France, 144 to every 100 females; in Italy, 140; in Belgium, 135; in Sweden, 133, and in Prussia, 129. In

New York, in 1891, the proportion was 137 males to every 100 females.

As regards nationality, in the same year, in New York, the still-births were in the proportion of 10 to every 100 live-births among the children of native parents, and only 6⅞ to the 100 among the children of foreign-born parents.

Sickness.—It is very difficult to procure sufficiently accurate data to enable us to judge well the actual amount of sickness in a community, and yet it is very important from an economical point of view that it should be known. A man who is sick enough to be incapacitated for work is a source of loss to the community until he recovers, and if he is ill enough to require the constant attendance of another person, there is so much additional loss. Most of the statistics we have upon this subject have been obtained from Mutual Benefit associations among workingmen, and from the reports of Army, Navy, and Police Surgeons. Such statistics apply only to male adults, and even then are the statistics of selected lives. From such sources Dr. Farr has estimated that for every death there are two persons constantly sick, or, stating the same thing in another way, there are two years of sickness for every death. He gives the following table regarding sickness and accidents among the laborers in the dockyards at Portsmouth and Woolwich:

	Mean number of workmen.	Days lost by sickness.	Days lost by accidents.	Constantly sick. Per cent.	Constantly suffering from accidents. Per cent.	Constantly ill from both causes. Per cent.
Portsmouth..	5,939	27,410	15,590	1.26	0.73	1.99
Woolwich....	2,243	10,593	8,594	1.29	1.05	2.34

The following table gives the number constantly sick to 100 living at different ages, and has been compiled from various sources by Farr. The statistics refer to members of English and Scotch benefit societies.

AVERAGE NUMBER CONSTANTLY SICK TO 100 LIVING AT EACH AGE.

Ages.	Friendly societies.				
	Scotland (Highland Society).	England (Ansell).	Scotland (Neison).	England (Neison).	East India Company's laborers.
20–30.....	1.14	1.54	1.65	1.69	1.62
30–40.....	1.32	1.83	1.66	1.91	2.06
40–50.....	1.97	2.56	2.44	2.89	2.69
50–60.....	3.60	4.32	5.17	5.21	6.58

The following table is of interest, showing the average loss of time by sickness per annum for males and females. It was prepared in 1884, for Sir James Paget, by the Actuary to the Registry of Friendly Societies, and is quoted by Newsholme:

Ages.	Population of England and Wales. Census of 1881.		Weeks sickness per annum, according to the experience of the Manchester Unity.		Average sickness per individual (per annum) in weeks.	
	Males.	Females.	Males.	Females.	Males.	Females.
15 to 20..	1,268,269	1,278,963	844,428	851,701	.666	.666
20 to 25..	1,112,354	1,215,872	820,183	896,685	.737	.737
25 to 45..	3,239,432	3,494,782	3,224,134	3,476,146	.995	.995
45 to 65..	1,755,819	1,951,713	4,803,760	5,368,229	2.736	2.751
All ages, 15 to 65..	7,375,874	7,941,330	9,692,505	10,592,761	1.314	1.334

These figures are made up from the experience of nearly 400,000 members, and may be considered approximately correct for the community at large. It will be noticed that, contrary to the general opinion, no more time is lost by sickness among the females than among the males, or, at least there is but a very slight excess, and that is entirely after the age of 45, the losses previous to that age being exactly the same in both sexes. The increase in the loss of time, which up to this age is very gradual, takes a sudden leap upward as the turning point of life is reached, and about three times as much time is lost by sickness between 45 and 65 as in the twenty years previous.

The following table shows the average duration of attacks of sickness, and was made up from returns of Scotch friendly societies by Mr. G. P. Neison:

Ages.	Total No. of attacks, including those ending in recovery and in death.	Total amount of sickness, including that ending in recovery and in death.	Average duration of each attack.
		Weeks.	Weeks.
10–15	12	39,428	3,286
15–20	117	749,571	6,407
20–25.....	637	2,830,285	4,443
25–30.....	985	5,483,000	5,566
30–35.....	1,074	5,014,143	4,668
35–40.....	872	4,524,714	5,188
40–45.....	758	4,158,714	5,486
45–50.....	519	3,445,714	6,639
50–55.....	537	6,634,285	12,354
55–60.....	491	7,171,571	14,606
60–65.....	350	9,102,286	26,004
65–70.....	135	5,934,714	43,960
70–75	116	8,867,999	76,448
75–80.....	29	4,588,857	158,236
80–85	19	4,027,000	211,947
85–90.....	0	.....	.....
90–95.....	1	353,000	353,000
	6,652	72,925,281	10,957

The following table is made up from the annual reports of the Police Department of New York City:

Year.	Number of days lost by sickness.	Total number of men in force.	Average number of days sickness to each man.	Average number of cases each day.	Total deaths per annum.	Number of days of sickness to each death.
1888...	31,780	3,328	9.5	87	40	2.2
1889...	34,122	3,398	10.0	93	37	2.5
1890...	39,339	3,502	11.2	108	41	2.6
1891...	45,848	3,623	12.6	126	48	2.6

The figures for 1889, 1890, and 1891 were raised somewhat above what might be considered normal by the prevalence of influenza, which was epidemic throughout the world.

IV. *Deaths.*—By far the most important data of vital statistics are those afforded by the deaths.

Death-rates are calculated in two ways: 1, As so many deaths per 1,000 of the living population; 2, as one death out of a certain number of the population; thus, if a village has a population of 1,000 and has 20 deaths in a year, we may give the death-rate as 20 per 1,000 living, or as 1 in every 50 living. The former method, introduced by Dr. Farr, is the one in most general use.

Besides these general death-rates, there are special death-rates calculated to subserve particular purposes, *e.g.*, to give an idea of the death-rate by sex, age, occupation, or in public institutions, or in proportion to the number of cases of sickness by particular diseases, all of which will be considered in their proper place.

All of these death-rates are usually estimated upon the same principle, which is to divide the number of deaths by one-thousandth part of the number of units to be considered, whether of population, cases of sickness, numbers engaged in any special occupation, etc. Thus, if in

a population of 5,000 there are 100 deaths in a year, the death-rate would equal $\frac{100}{5,000 \div 1,000} = \frac{100}{5} = 20$ per 1,000. In practice it is found to be much more convenient, instead of dividing the denominator by 1,000 (which would be awkward if decimal fractions remained), to multiply the numerator by 1,000, which amounts to the same thing, so that the formula for obtaining the death-rate would be $r = \frac{n \times 1,000}{p}$ where r is the rate, n the number of deaths, and p the population. In most towns which issue weekly mortuary reports, a weekly death-rate is given. These rates are really annual rates, and are supposed to indicate what the annual death-rate would be if the same number of persons died every week in the year. The total number of deaths in the week are therefore multiplied by the number of weeks in the year, which gives the total number of deaths that would occur in a year if the same rate of mortality continued throughout the year. The annual death-rate is then calculated in the manner previously described. In many towns the weekly deaths are multiplied by 52 in making out the death-rate, and this would be correct if there were just 52 weeks in the year. But there are 365.24226 days in the year, which is equal to 52.17747 weeks, and this is the multiplier used by the Registrar-General of England and in many places in this country. Thus, if a city contains 753,862 inhabitants and the total number of deaths for a week is 367, the death-rate would be equal to $\frac{367 \times 52.17747 \times 1,000}{753,862} = 25.4$.

These calculations are most easily and rapidly made by the use of logarithmic tables. It is the usual practice to make this estimate upon the mean population of the year, or the population in the middle of the year. It is evident that this makes the death-rates during the first six months a little smaller than they should be, as the population is really less than the number used in the estimate, and it makes the rates for the latter half of the year a little too large, for the real population is larger than that used in the estimate. In New York, it has been the practice for many years to divide the total increase of population for the year by the number of weeks in the year, so as to get the amount of weekly increase, and this is added week by week. A similar weekly addition to the population is made in Berlin, but there the estimate can be made with a fair degree of accuracy on account of the excellent police arrangements for keeping account of immigration and emigration, and the perfect system of registration of the births and deaths. As a matter of extreme refinement, the weekly increase might be calculated by extracting the 52.17747th root of the annual rate, but this would be a ridiculous attempt at accuracy; for, while theoretically correct, practically it would be useless, for the weekly death-rates are, in any event, of small value, excepting for comparing one year, or one season, with another in the same town. For purposes of comparing different towns with one another, they are practically of little value, on account of what mathematicians call the probability of error. This is greater in proportion as the number of data dealt with is smaller, and in the small number of deaths usually reported for a week, the mean or probable error is considerable. The mathematical formulæ for estimating the probable error are rather abstruse, but in the case in hand the mean or probable error may be considered to equal very nearly the square root of the number of deaths. This gives results that are somewhat too large, but is near enough to the truth to serve for ordinary calculations.

Thus, for example, in the instance already cited, how much might the death-rate vary from 25.4 without indicating any radical change in the sanitary condition of the town? Upon the supposition that the deaths were 367, the square root of which is 19, the deaths for the week might be either 386 or 348, without indicating any especial change in the sanitary condition of the town. This would mean a range of death-rate between 24.1 and 26.7. Dr. Billings, in the Cartwright lectures for 1889, gives the following illustration: "Suppose that in a village of 1,000 inhabitants there occur 25 deaths in the course of a year, and in a neighboring city of 10,000 inhabitants, there were 200 deaths in the same time. What is the probability that the death-rates of 25 per 1,000 for the first, and 20 per 1,000 for the second, indicate the relative healthfulness of the two places, supposing the data to be perfectly accurate, and that we have no other information in regard to them than that stated? The probable error for the village of 1,000 inhabitants, for 25 deaths, would be 5, and therefore the mortality in this place might vary between 20 and 30 per 1,000 without any certain indication of variation in the sanitary conditions of the place. In the city of 10,000 inhabitants, the probable error is a little less than 15, the variation between 185 and 215 corresponding to an average mortality of 18.5 to 21.5 per 1,000, there being a probable variation of only 3 per 1,000 instead of 10, as in the first case. It is very clear, then, that in comparing these two mortality-rates, no positive conclusion can be drawn as to the relative healthfulness of the two cities, seeing that the probable variations overlap, as it were, for the rates ranging from 20 to 21.5." General death-rates also, while not altogether meaningless in comparing the healthfulness of one town with another, are very misleading, unless the age-constitution of the populations of the two towns is similar. A marked difference in this respect may give rise to the singular paradox, that a city which is actually healthier than another may have a higher death-rate. This depends upon the fact that the death-rate is very much higher at some ages than at others. The mortality of infants under one year of age is very great, and also of people over sixty years of age, while the mortality of children between ten and fifteen is exceedingly low, and that of adults between twenty and forty is but little higher. Now, as the age-constitution of the inhabitants of different cities is seldom the same, it follows that in comparing the sanitary condition of one city with another, by means of the death-rate, the age-constitution has to be taken into account. The varying ages of the populations affect the result in precisely the same way as the varying amount of the components of a mixture affect the price of a compound, as explained under "alligation" in the common arithmetic. Different kinds of sugar, at different prices, may be mingled in different proportions so as to make mixtures of various prices. Let the following serve as an illustration: Suppose two cities, A and B, to have 100,000 population each. In A the death-rate for a particular year is 17.28 per 1,000, and that of B for the same year is only 16.70. Is B therefore in a healthier sanitary condition than A? Such a conclusion is often accepted as justified, but the table below will show that the reverse might be the case in certain contingencies. Of course, in preparing a schematic table like this, the age-proportions are a little forced and exaggerated, in order to bring out the salient points as boldly as possible, and do not represent in themselves the probable age-constitution of any actual community.

Age.	Number at each age.		Deaths per 1,000 at each age.		Total deaths at each age.	
	A	B	A	B	A	B
Under 5.....	25,000	15,000	60	70	1,500	1,050
5 to 14.....	22,000	20,000	8	10	176	200
15 to 24.....	20,000	25,000	7	8	140	200
25 to 44.....	24,000	30,000	18	20	432	600
45 to 64.....	7,000	8,000	40	50	280	400
65 and upward...	2,000	2,000	100	110	200	220
	100,000	100,000			17.28	16.70

Thus it is shown that, owing to a smaller population at the ages when mortality is high and a larger one at ages when the mortality is low, the death-rate for all ages, *i.e.*, the general death-rate as usually calculated, is less in B

than in A, although the death-rate at each age is considerably higher, and therefore the sanitary condition of the place must be considered inferior.

General death-rates, therefore, although valuable for estimating the varying condition, as regards health, of the same community in different years and different seasons, because the age-constitution of such a community remains virtually constant for considerable periods, must be used with reserve in comparing different communities, unless accompanied by a statement of ages, etc., which will enable the proper corrections to be made.

A similar source of error lies in the varying proportion of the sexes in different communities. The death-rate of males is always higher than that of females at each age, excepting for a few years before and after puberty, and the general death-rate of males is always highest. The following table shows the average annual death-rates of males and females in England at certain ages for a period of fifty years, viz., from 1838 to 1888:

	Under 5.	5 to 9.	10 to 15.	15 to 19.	20 to 24.	25 to 34.	35 to 44.
Males	69.5	7.8	4.4	6.1	8.2	9.4	13.0
Females	59.7	7.5	4.5	6.6	7.8	9.4	12.0

	45 to 54.	55 to 64.	65 to 74.	75 to 84.	85 and upward.	All ages.
Males	18.9	32.8	67.7	147.6	313 1	22.7
Females	15.6	28.0	59.9	134 2	287.7	20.5

If now the population of A consists of 40,000 males and 60,000 females, and the population of B of 60,000 males and 40,000 females, assuming the general death-rates per sex to be given above, there would be a general death-rate of 21.44 in A and of 21.86 in B, the difference being due solely to the difference in sex-distribution. An excess of females, therefore, in any town, tends to lower the death-rate, and an excess of males to raise it.

It is evident that, in order to make proper comparison between different towns by means of the general death-rates, some method must be devised by which these rates may be corrected, so as to allow for the effect of a different age and sex distribution of the population. The following method is used by the English Registrar-General in his annual reports. In the first place he adopts as a standard death-rate the death-rate at all ages calculated upon the supposition that the rate at each age-period in each town was the same as in England and Wales during the last previous inter-censal period of ten years. The following table, taken from Newsholme, shows the method of obtaining the standard death-rate for the city of Brighton.

Ages.	Mean annual death-rate for England and Wales. 1871 to 1880.		Population of Brighton in 1881.		Calculated number of deaths.	
	Males.	Females.	Males.	Females.	Males.	Females.
Under 5	68.14	58.10	6,213	6,371	423.35	370.16
5 to 9	6.67	6.20	5,655	5,533	37.70	34.30
10 to 14	3.69	3.70	5,294	5,447	19.53	20.15
15 to 19	5.23	5.43	4,480	6,512	23.43	35.36
20 to 24	7.32	6.78	4,326	6,398	31.67	43.37
25 to 34	9.30	8.58	7,217	9,927	67.12	85.17
35 to 44	13.74	11.58	5,356	7,305	73.59	84.59
45 to 54	20.05	15.59	3,910	5,552	78.40	86.55
55 to 64	34.76	28.54	2,707	3,988	94.09	113.82
65 to 74	69.57	60.82	1,409	2,343	98.02	142.50
75 and upward	169 08	155.83	631	974	106.69	151.78
			47,196	60,350	1053.59	1167.75

Now, the total population being 107,546 and the total number of calculated deaths being 2221.34, the death-rate will be 20.66, which constitutes the "standard death-rate" for Brighton in 1881. But the general rate for England and Wales, in 1871 to 1880, was 21.27, and the rate for Brighton being lower, shows that the age and sex distribution of the population was more favorable to a low mortality than in the whole of England and Wales; and in fact it is found by comparison, that the proportion of the population living of the ages when the mortality is high, is lower in Brighton and vice versa, *e.g.*:

Age, Distribution of Population, 1881.

	All ages.	Under 5.	5 to 9.	10 to 15.	15 to 19.	20 to 24.
England & Wales.	1,000	136	120	108	98	90
Brighton	1,000	117	104	100	103	99

	25 to 34.	35 to 44.	45 to 54.	55 to 64.	65 to 74.	75 and upward.
England and Wales	146	113	84	59	33	13
Brighton	159	118	88	62	35	15

The difference in the death-rate, it is readily seen, is due to a smaller number of persons under fifteen, and a larger number above that age. In order now to compare the death-rate of Brighton with that of other towns, its rate must be increased in the ratio of 20.66 to 21.27, *i.e.*, by 1.0296. This is called the factor for correction for age and sex distribution by which the death-rate of Brighton must be multiplied in any year in order to make it comparable with that of England and Wales, or with other towns whose rates have previously been corrected in the same manner. This standard death-rate, once obtained, is found to hold good throughout the decennium, until another census renders it possible to substitute a new one.

In this way a table is prepared which shows what the death-rate of each town would have been in any year, if the age and sex distribution of its population had been the same as that of the entire population of England and Wales. A portion of such a table is given below:

Towns.	Standard death-rate.	Factor for correction for age and sex distribution.	Recorded death-rate.	Corrected death-rate.
Brighton	20 66	1.0296	16.88	17.38
Hull	20.62	1.0316	19.25	19.86
London	20.04	1.0615	19.57	20.77
Birmingham	19.95	1.0663	19.72	21.03
Bristol	20.55	1.0351	20.39	21.11
Leeds	19.90	1.0689	21.06	22.51
Sheffield	19.78	1.0754	21.60	23.23
Cardiff	19.60	1.0853	21.92	23.79
Liverpool	19.39	1.0971	23.70	26.00
Manchester	19.09	1.1143	28.67	31.95

As remarked by the Registrar-General (Annual Summary, 1883), "It may naturally be asked, of what use are the general death-rates, as usually given, if they cannot be accepted without further and considerable correction? In the first place, if the death-rate in any given town or area in one year be compared with its death-rates in other years, no correction is required; for the age and sex distribution in an individual town or other area remains practically constant; and, secondly, although it is doubtless true that the general death-rates of towns or other areas cannot safely be used for accurate comparison between such towns or areas in respect of healthiness without further correction, yet they serve as a very valuable approximate indication; for if the column 3 be compared with column 4, it will be seen that whether the towns be arranged according to their recorded or according to their corrected death-rates, the order will scarcely be changed. The correction simply alters the amount of difference between the towns, leaving the position in which they

stand to each other but slightly changed." (Quoted by Newsholme.)

It is found in England that correction of the death-rates in this manner, as a rule, raises the death-rates of towns, and diminishes those of the rural districts, thus emphasizing the fact that the constant immigration into the towns tends to swell the number of the population at the ages when the mortality is lowest.

Newsholme quotes from Dr. Ogle a comparison of this sort made between two countries. In 1881 the general death-rate in England and Wales was 18.9 per 1,000 of all ages, while the general death-rate in France was 22.0, *i.e.*, 3.1 higher than England. But had the age-distribution of the French population been identical with that of the English population, the French general death-rate would have been 20.9, and not 22.0. Thus of the 3.1 difference between the two rates, 2.0 was due to difference of health condition, and 1.1 was due to difference of age-distribution.

Effect of Birth-rate upon Death-rate.—It has been already mentioned under Births, that a high death-rate among infants is generally followed by a high birth-rate, because the intervals of child-bearing become shorter, it being the practice with many, perhaps the majority of mothers, among the poor especially, to suckle their infants as long as possible in order to avoid pregnancy. On the ground that a high birth-rate results in a greater proportion of infants in a given population, and that the mortality among infants is very high even under the most favorable circumstances, it has been held, especially by Dr. Letheby and his supporters, that a high birth-rate always means a high death-rate, and as a high birth-rate is taken as an index of prosperity, being intimately connected with a high marriage-rate, it has also been maintained with great vigor that a high death-rate was an indication of the prosperity of the community. Dr. Farr, however, in the celebrated discussion which took place on this question, showed conclusively that a high birth-rate results in a low death-rate, because the constant addition of so many children to the population prolongs its effects over into the ages when the mortality is lowest, and so eventually produces an age-distribution of the population, in which there is a great excess of persons at the very healthiest time of life.

In the Cartwright lectures Dr. Billings has estimated the effect of a constantly high birth-rate in the following manner: "Starting with a population numbering in all 308,378, supposing that there are no migrations, we will calculate the progress of such a population for one hundred successive years, under two suppositions: the first for a constant birth-rate of 35 per 1,000, and the second for a constant birth-rate of 45 per 1,000. The death-rate at the commencement, say, is 32.42 per 1,000. Under the influence of a constant birth-rate of 35 per 1,000, this death-rate will increase during the first period of five years to 33.17, and after that steadily sink until, at the end of fifty-five years, it becomes less than the original death-rate, and at the period of sixty-five years will sink below it; after which it again rises until, at the end of one hundred years, it has reached the rate of 32.44.

"Taking now the same population, under the same circumstances, at a constant birth-rate of 45 per 1,000, we see that the death-rate rises in the first five years to 36, after which it steadily sinks as it did in the former case, until, after the lapse of sixty years, it is only 32.01, after which it again rises, and finally comes down to a point a little below that from which it started. In both these cases, then, it is evident that the high birth-rate for a time produces an increased death-rate, since there are no other circumstances present to account for the change. But after the first five years the proportion of those living at the ages at which there is the lowest mortality has been so much raised as to more than counterbalance the large numbers living in the first years of life, and, therefore, the death-rate steadily descends.

"But, to understand the full effect of this change it is also necessary to consider the average age at death. Taking the average age at death at 31.37, it will decrease to 29.65 under the influence of a constant birth-rate of 35 per 1,000; while, with the higher birth-rate of 45 per 1,000, it will diminish as the death-rate diminishes to the age of sixty-five, at which period it will be only 23.02, after which it will again rise as the death-rate increases."

Effects of Immigration.—The tendency of immigration is to lower the death-rate, because the majority of immigrants are men and women of mature years and of the most vigorous period of life. They are people who, as a rule, have the greater part of their lives before them, and if they come in sufficient numbers to form an appreciable proportion of the population, the death-rate is materially lowered. For this reason, among others, the death-rate of cities does not fairly represent their true sanitary condition, because there is a constant influx into them of young men and women from the country, of just the healthiest age, who are seeking their fortunes either in industrial or professional pursuits, or in domestic service. The death-rates of cities would be much higher than they are, if the increase in size was due solely to the excess of births over deaths. The same cause tends to increase the death-rate in countries and localities from which the emigration takes place, because they are continually losing the most vigorous and healthy individuals, leaving the population with an excess of persons of the ages when the mortality is highest, viz., the very young and the very old.

Climate.—The effect of climate on the mortality is very marked. In an equable climate, where changes of temperature are very gradual, and the extremes are not widely separated, the death-rate, other things being equal, will be much lower than where such changes are sudden, and the range of temperature is very great. Such contrasts of temperature are well shown in the cities of England as compared with the cities of the Northern United States. In London, a temperature of 90° F. in summer, or of zero in winter, is practically unknown, while in this country such temperatures may be expected every year. The following table shows this very clearly:

TEMPERATURES IN LONDON AND NEW YORK IN 1888.

	London	Month.	New York.	Month.
Highest day temperature	87.7°	August	96°	June
Lowest night temperature	18.4°	Feb.	0°	Jan.
Average for year of the maximum temperature by months	67.7°		73.5°	
Average for year of the minimum temperature by months	32.0°		27.7°	
Average of monthly means of daily maximum temperature	55.8°		74.7°	
Average of monthly means of daily minimum temperature	41.3°		30.3°	
Mean monthly temperature averaged for year	47.7°		49.33°	
Highest monthly mean	59.1°	August	72.56°	August
Lowest monthly mean	35.0°	Feb.	22.97°	Jan.

The effect of such a climate is shown in the figures of seasonal mortality. In England the summer months are the healthiest of the year, while in New York they are the deadliest, as shown in the following table;

Place.	Year.	Death-rates.			
		First quarter.	Second quarter.	Third quarter.	Fourth quarter.
England Urban Districts	1881	22.6	19.2	18.3	20.2
New York City	1881	29.14	30.40	35.07	28.83

In London, and, in fact, in Western Europe generally, deaths from thermic fever or sunstroke are very uncommon, while in the northern cities of the United States the reverse is the case. In New York City there have been as many as 320 in a year, and 68 in a single day. Such extreme heat is accompanied by a great mortality from diarrhœal diseases, especially among infants. It also causes indirectly the death of hundreds of persons who have been enfeebled by disease, and who, but for

the heat, might have recovered, or at least had their lives considerably prolonged. In London the fogs of November cause a greatly increased mortality from diseases of the respiratory organs, while in this country it is the most healthy month of the year.

Effect of Season.—It has been found that the prevalence of different diseases varies very greatly with the season. Some, like typhoid fever, are most prevalent in the autumn; others, like diarrhœal diseases, and especially cholera infantum, in the summer; some, especially the exanthematous diseases, in the winter and spring; while the hot weather is particularly fatal to the young, and cold weather to the aged. The following table shows the relative prevalence of certain diseases at different seasons of the year. (J. Netten Radcliffe, in Quain's "Dict. of Medicine," Art. Periodicity in Disease.)

	Winter.			Spring.			Summer.			Autumo.		
	Jan.	Feb.	Mch.	Apr.	May.	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.
Small-pox	+	+	+	+	±	+	−	−	=	−	−	−
Measles	+	−	−	−	+	±	+	−	−	−	+	±

Old age	±	+	+	+	−	−	=	−	−	−	−	+

\+ Above the average. ± Maxima. − Below the average. = Minima.

It is also to be noted that some diseases appear to recur after a certain number of years have elapsed, with some regularity, especially the contagious and infectious diseases. Thus it has been noticed in New York City, that scarlet fever and diphtheria, although more or less prevalent all the time, tend to reach a maximum every 3 or 6 years, *e.g.*, there were maxima of scarlet fever in 1870, 1873, 1879, 1882, 1888, and 1891, and of diphtheria in 1869, 1875, 1878, 1881, and 1887. This is undoubtedly partly due to the fact that the persons who are susceptible to these diseases are gradually attacked by them, as they become more and more prevalent, until all of the susceptible material has been exhausted, or the susceptible persons are so widely separated that there is no opportunity for the operation of the ordinary laws of infection. But, by birth and growth every few years, so many new susceptible persons are added to the community, that the distances between the centres of contagion are bridged over, so to speak, and new epidemics are started. So, too, as the epidemics of Asiatic cholera are often attributed to the Mecca pilgrimages, and as those occur annually, there should be a spread of cholera westwardly every year, instead of at long intervals, unless some influence is at work which is not yet recognized.

Public Institutions.—It is evident that if the deaths in public institutions are charged to the locality in which the institutions are situated, the death-rate of that locality will be considerably higher than that of the region round about it. The deaths in such houses, therefore, must be redistributed to the districts from which the patients came, and this is quite commonly done. But there are many deaths in public institutions which cannot be referred back to a former residence in which the disease may have been contracted, and they must be accounted for in the final estimation of the death-rate in some other way. Such are deaths in foundling asylums, in maternity hospitals (of children who were born in the hospital), of many inmates of almshouses, who have lived in them for many years, of old people whose only home for a long period has been a home for the aged, etc. These various sources of error would seem, at first sight, to vitiate local death-rates in a high degree, and so they would if they were left entirely uncorrected. The best way would seem to be to redistribute the deaths, so far as is possible, to the places from which the patients came to the institution; but if this is done, the population of the institutions should also be redistributed in the same way. This is not always possible, and if it were there would remain a certain proportion of population and deaths that could not be redistributed. This proportion is always comparatively small, and can be best disposed of by redistributing the population to the different districts or subdistricts in proportion to their population, and then also redistributing the deaths to the same localities proportionately to the number of deaths in each.

In the United States, where it is so difficult in many cases to procure the necessary information regarding the inmates of institutions, probably the best way would be to reapportion the total population and deaths of public institutions in the manner above indicated, without any attempt at making an accurate redistribution. The possible error in such case would be very small, although a certain proportion of the inmates of the institutions and of the deaths in them would, of necessity, be added to the population and deaths of some sections of a large city, largely occupied by the wealthy people, who, as a matter of fact, have hardly anything to do with the public institutions, excepting as patrons.

Effect of Race.—The death-rate, both general and special, is seriously affected by race or nationality. Some nationalities are especially prone to certain diseases, and if the sanitary environment favors these diseases, as for example overcrowding favors phthisis and diarrhœal diseases, the mortality of those who are most susceptible may greatly exceed that of those who are least susceptible. The following table shows the death-rate of various European nationalities for several years:

	Average 20 years. 1861 to 1880.	1882.	1883.	1884.	1885.	1886.	1887.	1888.	1889.
Austria	31.1	30.8	30.1	29.4	30.1	29.4	28.8	29.2	27.3
Belgium	22.8	20.2	20.8	20.9	20.1	21.1	19.3	20.1	19.1
Denmark	19.7	19.3	18.4	18.4	17.9	18.2	18.3	19.7	18.6
England, Wales,	21.9	19.6	19.5	19.5	19.0	19.3	18.8	17.8	17.9
France	23.6	22.2	22.2	22.2	21.9	22.5	22.0	21.8	20.5
German Empire	26.9 (9 yrs.)	25.7	25.9	26.0	25.7	26.2	24.2	23.8	23.8
Holland	24.7	20.7	21.8	22.2	21.0	21.8	19.7	20.4	20.1
Hungary	36.1	35.3	32.0	30.8	31.6	31.4	33.5	31.7	....
Ireland	17.5	17.4	19.2	17.6	18.4	17.9	18.3	18.0	17.5
Italy	20.0 (18 yrs.)	27.5	27.5	26.7	26.6	28.3	27.5	26.8	24.9
Norway	16.9 (10 yrs.)	18.4	17.1	16.4	16.5	16.1	16.0	16.9	17.4
Prussia	26.8	25.4	25.6	25.7	25.4	26.1	23.9	22.9	23.2
Scotland	21.9	19.3	20.1	19.4	19.1	18.6	18.7	17.6	18.0
Sweden	19.2	17.4	17.3	17.5	17.8	16.6	16.1	16.0	....
Switzerland	23.6 (11 yrs.)	21.9	20.4	20.2	21.3	20.7	20.2	19.9	20.3

The differences in the death-rates in this table are, of course, not entirely due to the difference of nationality, but this undoubtedly has some effect, for it is shown in other ways. In the United States census for 1880, a table is given from which the following is an extract:

Cause of death.	Death-rates per 1,000 deaths from all causes.			
	White.	Colored.	Irish parentage.	German parentage.
Alcoholism	2.5	0.7	6.7	2.7
Cancer	19.1	7.8	24 3	25.8
Consumption	126.2	139.1	198.4	123.6
Croup	26.1	21.8	15.1	23.2
Diphtheria	39.8	17.4	42.1	72.7
Diseases of nervous system	119.1	96.9	94.7	109.4
Heart disease and dropsy	58.1	64.5	62.3	60.9
Malarial fever	30.7	48.3	12.9	14.1
Measles	9.1	17.7	5.3	8.5
Pneumonia	82.5	105.5	89.1	82.1
Scarlet fever	20.9	3.9	24 0	30.1
Suicide	3.2	0 5	2.7	7.2
Typhoid fever	33.9	31.7	17.4	29.6

Vital Statistics.

The greater liability of the Irish to phthisis and of the Germans to diseases of the nervous system, appears plainly here, as in every table of the kind that is constructed. The tendency of the Germans to commit suicide is also well known, appearing by this table to be about three times as strong as that of the Irish. In the mortality statistics of New York City, some of these tendencies are even more plainly indicated. Thus the numbers of Irish and Germans in the population are pretty evenly balanced; *e.g.*, in 1880 there were 198,595 Irish and 163,482 Germans, a difference of about twenty per cent., and there is no reason to suppose that this ratio has changed in any great degree since. If it has changed, the change has probably been in the direction of an increased proportion of Germans, making these two elements of the population more nearly equal than before. Now, in 1891, there died of phthisis 1,204 Irish, and only 663 (a little more than half as many) Germans; while of diphtheria there died 6 Irish, and 20 Germans. Out of 300 deaths by suicide, only 27 were Irish, and 106 (more than one-third of the entire number) were Germans. This proneness of the German to commit suicide when he is dissatisfied with the way things are going, is probably not altogether a blood defect, due to a more saturnine temperament, but is partly owing to his less religious nature. The figures first given apply only to the foreign-born, but the offspring of Irish and German parents show the same tendencies. For example, in the same year, 1891, the deaths from phthisis of the children of Irish parents numbered 2,158, against 1,009 of German; the deaths from diphtheria were 240 of German parentage, against 167 of Irish; and the deaths from suicide were 115 of German, against only 40 of Irish parentage. Italians show a marked susceptibility to acute diseases of the respiratory organs, and also to measles, which seems to be especially fatal to children of Italian parentage.

The general death-rates according to nationality, for New York City, are not yet available from the census of 1890, but the census of 1880 gave the following results:

Nationality.	Population.	Deaths.	Death-rates.
Austro-Hungary	8,844	126	14.25
Belgium	556	47	84.53
Bohemia	8,093	75	9.27
British America	7,004	148	21.13
China	747	16	21.42
Denmark	1,096	24	21.90
France	9,910	157	15.84
German Empire	163,482	3,258	19.93
England	29,664	621	20.93
Ireland	198,595	5,565	28.02
Scotland	8,683	191	22.00
Holland	1,860	34	18.28
Italy	12,223	265	21.68
Russian Poland	13,571	131	9.65
Spain	669	14	20.93
Sweden	3,194	77	24.11
Switzerland	4,545	102	22.44
Total population	1,206,299	31,937	26.47

The comparatively low death-rate for most of the foreign-born is chiefly due to the fact that so large a proportion of them are adults, mostly between the ages of fifteen and fifty, when the mortality is low. As New York is composed in great part of such elements, it is plain that the death-rate of that city is much lower than it actually should be, and does not properly represent its sanitary condition.

In 1890 a tenement-house census was taken of the city of New York, and the results, as published in the Annual Report of the Health Department for 1891, threw some light upon the mortality-rates as regards nationality. Although the nationality of tenants was not taken in the census, the population was divided up into small districts in such a way as to give the death-rates of considerable masses of people, who were almost entirely of one nationality or race. Thus the district between the Bowery and Norfolk Street, bounded north and south by Grand and Division Streets, is inhabited almost exclusively by Russian Jews, and the death-rate in the population of 35,190 was only 61.15 for children under five years of age, and 7.59 for persons five years old and upward. In a portion of the Fourth Ward chiefly occupied by Italians, the death-rate of children under five was 119.02, and of persons five years old and over, 21.29. In special diseases, also, the death-rate of the Russian Jews was unusually low, exhibiting in a striking light the strong vitality of the race, which may be due partly to their frugal and abstemious way of living, as well as to the inherent race vigor.

Effect of Marriage.—The statistics most frequently quoted upon this point are those of Dr. Bertillon, compiled from the reports of France for a series of years, which seem to show that marriage has a very beneficial effect as regards longevity on both the man and the woman. The following table from Newsholme is taken from Dr. Bertillou's figures for the years 1856–1865, a period of ten years.

Death-rate per 1,000 Living of Married and Unmarried.

Ages.	Males.			Females.		
	Single.	Married.	Widowers.	Single.	Married.	Widows.
20–24	12.88	8.92	49.60	8.32	9.92	12.31
25–29	10.17	6.24	21 84	9.02	8.98	23.62
30–34	11.51	6.82	19.17	9.87	9.36	16 90
35–39	13.15	7.52	17.50	10 87	9.29	15.03
40–44	16.62	9.55	18.89	13.28	10.14	12.73
45–49	19.60	11.47	22.20	15.71	14.69	13.30
50–54	25.80	15.61	26 80	20.97	19.11	15.20
55–59	32.10	21.50	34.17	26.90	19.29	24 47
60–64	45.92	32.60	47.50	40.52	30.75	37.07
65–70	58.50	44.80	62.97	58.30	45.30	53.50

This table gives some curious results. The mortality of married men and women as will be seen, is lower than that of bachelors and spinsters at every age period, and also much lower, as a rule, than that of widowers and widows. The mortality of widowers is higher than that of bachelors at every age, while that of widows is higher than that of spinsters up to the age of forty, after which it becomes lower. The extraordinary death-rate of widowers under twenty-five, which also showed itself in a similar manner in a previous table quoted by Dr. Farr, must be due to insufficient data, for the number of widowers at so young an age must be very small.

It has been objected to these statistics, that although they prove the greater healthfulness of married persons, they do not and cannot prove that this greater healthfulness is due to the permanent association of the man and the woman in the same home. It must be borne in mind that, at the start, it is the stronger, more vigorous, and independent of the race who marry, while the bachelors are often lacking in the qualities that attract a mate, and so, by a process of natural selection, the stronger ones are chosen to perpetuate the race. Then married men generally lead more domestic lives, keep more regular hours, and in various ways live under healthier conditions, entirely unconnected with the sex-relation.

Occupation.—The most successful investigations, with regard to the effect of occupation on health and on the death-rate, have been made on a limited scale by private individuals. In the taking of a census it is impossible to procure the minute information which is necessary in order to have particulars about occupations of much value. The name printer may include pressmen or compositors, who are exposed in the prosecution of their trade to very different influences. The word merchant also may include persons whose life, on the whole, is an easy one, and those who are daily harassed by petty detail work, very exhausting and unsatisfactory. The physician may either be a city specialist, with fixed office hours and considerable leisure time, or the head of a public institution, with a fixed income and spacious and sani-

tary surroundings, comparatively free from care and with only moderate responsibility, or he may be practising in the country, obliged to take long journeys over rough roads, often in stormy weather, irregular in his hours of sleep and eating, and early worn out. Moreover, in a country like this, where there is much shifting about from one occupation to another, many men passing the latter half of their lives in an entirely different occupation from the first half, another element of uncertainty is introduced. Then, too, there is in every country the lack of precise data due to the graduation of the individual from one rank in his business, trade, or profession to another. It is inevitable, for instance, that the longevity of professors should be greater than that of students, or that proprietors of any kind, manufacturers, the presidents of large corporations, etc., should be older, on the average, when they die than those employed under them, because of the comparatively few young men among them, whose early death among employees tends to reduce the mean age at death. So with seamstresses and domestic servants of all kinds, especially females, who often leave that occupation when they marry. So that any classification of female workers of any kind is liable to contain an unusual excess of young people, when compared with like occupations among males.

Special investigations, however, have been made in this direction, notably in England, where Dr. Farr carefully compiled a table showing the death-rates for several selected occupations, with proper precautions to avoid, as far as possible, all known sources of error. Dr. Farr's figures covered the years 1860–1861, and 1871. Dr. Ogle has since compiled similar statistics for the three years 1880–1882. The two sets of results are here given (taken from Newsholme).

MEAN ANNUAL DEATH-RATES PER 1,000 LIVING.

Occupation.	1860–1. 1871. Ages.		1880–1–2. Ages.	
	25 to 44.	45 to 64.	25 to 44.	45 to 64.
Clergymen	5.96	17.31	4.64	15.93
Gardeners	6.74	17.54	6 52	16.19
Farmers	7.66	17.32	6.09	16.53
Schoolmasters	9.82	23.56	6.41	19.98
Fishermen	11.26	15.84	8.32	19.74
Carpenters	9.44	21.36	7.77	21.74
Lawyers	9.87	22.97	7.64	23 13
Tanners	10.43	26.57	7.97	25.37
Shoemakers	10 39	22 30	9.31	23.36
Drummers (comm.)	12.28	29.00	9.04	25.03
Bakers	10.72	26.39	8.70	26.12
Bricklayers	11.43	27.16	9.25	25.59
Blacksmiths	10.07	23.88	9.29	25.67
Tailors	12.92	24.79	10.73	26.47
Printers	13.02	29.38	11.12	26.60
Physicians	13.81	24.55	11 57	28.03
Butchers	13.19	28.37	12.16	29.08
Plumbers	12.48	34.66	11.07	32.49
Cutlers	11 88	32.74	11.71	34.42
Brewers	19.26	36.86	13.90	34.25
Cab drivers	15.94	35.28	15.39	36.83
Liquor dealers	18.01	34.14	18.02	33.68
File-makers	16.27	42 30	15.29	45.14
Street peddlers	20.09	37.82	20.26	45.33
Laborers (city)	18.35	40.64	20 62	50.85
Hotel servants	21.91	42.19	22.63	55.30

When we come to discuss the relation of special diseases to occupation, the problem becomes still more difficult, on account of the enormous amount of data to be sifted and compiled. Accordingly the most that can be done is to take a comparatively small list of occupations and a small number of the most prominent causes of death, and make up a table by combining them. Moreover, it is exceedingly difficult to obtain accurate information with regard to such causes of death as alcoholism and syphilis, on account of the tendency to give the results of these causes, without mentioning the cause, out of sympathy with the surviving members of the family, who do not like to have the true cause spread upon the public records. The real cause of death, as influenced by the occupation, has to be in a measure inferred, as it may be from the following table from Dr. Farr's supplement to the Registrar-General's thirty-fifth annual report.

ANNUAL RATES OF MORTALITY PER 1,000, AT FOUR AGES AMONG CLERGYMEN, PROTESTANT MINISTERS, AND AMONG PUBLICANS AND WINE MERCHANTS.

Ages.	Clergymen.	Protestant ministers.	Publicans, beer sellers, wine and spirit merchants.
25–34	4.65	5.83	14.49
35–44	6.28	7.30	20.44
45–54	13.24	9.33	28.59
55–64	22.70	24.60	43.03

"Dr. Ogle's figures for 1871–80 show that the mortality from liver diseases (perhaps the most trustworthy test of alcoholic excess) is six times as high among innkeepers and publicans, and two and a half times as high among brewers, as among the generality of males." (Newsholme.)

Of other poisons giving rise to special forms of chronic disease, the most prominent, next to alcohol, is lead. Four occupations, according to Newsholme, especially expose workers to lead-poisoning, viz.: plumbers, painters, earthenware-makers, and file-cutters. During the four years 1879–82, 229 deaths of males were ascribed to this cause, distributed among various occupations as follows:

House-painters	91	Iron-moulders	2
Plumbers	28	Calico-printers	2
Earthenware-makers	16	Paint, color-makers	2
File-cutters	14	Glazier	1
Lead-workers	8	Artist	1
Printers	6	Lead-roller	1
Lead-miners	3	Lead-mine agent	1
Gas-fitters	3	Caulker	1
Coach-painters	3	Children (under 15)	6
Whitesmiths	2	Others	36
Glass-cutters	2		

Of 64 deaths of plumbers, on the other hand, in New York City, in the two years 1879–80, not one died of lead-poisoning, but more than a third, 22, died of phthisis, and 10, an additional sixth, of pneumonia.

Relations of Density of Population to Mortality.—It had long been known in a general way that the crowding together of human beings increased the mortality among them, but it was reserved for Dr. Farr to show that this mortality increased with increasing density with such regularity that a fixed formula could be furnished, which should enable comparisons to be made, and the probable death-rate of one locality computed from the known death-rate of another, if the density of the population were known in both.

The density of the population is usually indicated by the statement that so many persons to the square mile are living in the area under consideration. Or it may be given as so many to the acre, or conversely, as so many acres or square miles, or fractions of either to each person. In making his computations, Dr. Farr used the more common of these methods, which is the first one. The first formula he fixed upon was the following one: Let m = the mortality in any group of persons, m' a higher mortality in any other group, D = the density of population in the first group, and D' the density of population in the second group, then $\frac{m'}{m} = \sqrt[6]{\frac{D'}{D}}$, that is, the mortality in different districts varies as the sixth root of the population in these districts. After frequent trials of this formula, Dr. Farr changed it to the statement that the mortality varied very nearly as the eighth root of the density, or more exactly, using instead of $\frac{1}{8}$, the fraction 0.11998 or 0.12, so that the expression in the formula would be $m' = m\left(\frac{d'}{d}\right)^{0.11998}$. The difference in the re-

sults obtained by the two formulas, however, is very slight, so that they are practically the same.

Thus, if in three hundred and forty-five groups of districts with a mortality of 19.2, the density was one hundred and eighty-six persons to a square mile, then, in nine groups of districts with a density of 4,499 to the square mile, what was the mortality? The method of ascertaining the answer to this question would not be by working out the following proportion, viz. : 186 : 4,499 : : 19.2 : x, but this, viz. : $(186)^{0.12}$: $(4.499)^{0.12}$: : 19.2 : x, which would give a calculated mortality of 28.08.

As an illustration of the close correspondence between death-rates calculated by this formula, and the actual rates as determined by the recorded deaths, the following table is of interest :

Rates of observed and calculated mortality in seven groups of districts in England, outside of London :

	1	2	3	4	5	6	7
Number of persons to square mile.....	166	186	379	1,718	4,499	12,357	65,823
Observed mortality....	16.75	19.16	21.88	24.90	28.08	32.49	38.62
Calculated mortality...	18.90	19.16	20.87	25.02	28.08	37.70	38.74

Dr. Farr found that the calculated rates for different localities corresponded so closely with the actual ones, when other sanitary conditions appeared to be identical, that he proposed that in any inquiry relating to the sanitary condition of a community or locality, the death-rate should be first calculated from the comparative density of the population, and when the real death-rate was above or below this, the causes of the variation should be investigated.

It has been found that while Farr's law holds good to a remarkable degree with very dense populations, there is more lack of correspondence between observed and calculated rates where the population is sparse. And this was really to be expected, for, as far as the effects of crowding are concerned, it can make little difference to a family whether the adjoining house is two hundred or four hundred feet away.

The evil effects of overcrowding are more intensely felt by the very young, who are more susceptible to all the influences that tend to impair the health. This is well shown in the following table, given by Newsholme, and representing the same seven groups of districts in England just quoted in connection with Farr's law.

	1	2	3	4	5	6	7
Number of persons to a square mile..	166	186	379	1,718	4,499	12,357	65,823
General death-rate at all ages..... ..	16.94	19.18	21.90	24.81	28.02	32.92	38.67
Death-rate of children under 5	37.80	47.53	63.06	82.10	94.04	111.90	139.52

It will be noticed that while the death-rate for all ages, in the densest population is but a little more than twice that of the sparsest, the death-rate of children under five years of age is more than trebled.

In many parts of England it is the practice to build what are called back-to-back houses, *i.e.*, houses where rear walls are in contact or nearly so, so that through and through ventilation is impossible. These houses are occupied, as a rule, by the poorer people, and show clearly the effects of crowding, when the air is so confined that the results of density of population have full play.

The Salford statistics, prepared by Dr. Tatham, present this in a clear light, as seen in the following table :

		Population.	General death-rate.	Death-rate from phthisis.	Death-rate from diarrhœa.
Greengates Subdistrict.	I. No back-to-back houses.	8,713	27.5	2.8	1.42
	II. Average of 23 per cent. of back-to-back houses	11,749	29.2	3.3	1.55
	III. Average proportion of 56 per cent. of back-to-back houses	11,405	30.5	3.6	2.12
Regent Road Subdistrict.	I. No back-to-back houses	54,264	26 1	2.7	1.54
	II. Average of 18 per cent. of back-to-back houses	8,773	29.1	2.7	1.85
	III. Average of 50 per cent. of back-to-back houses.....	4,380	37.3	4.5	2.83

On the other hand, in New York City, it has been noticed that the larger houses, which contain more people on a single lot of land (containing 2,500 square feet), do not show the effect of crowding so much as might be expected. The following table is taken from the report upon the Tenement-house census of 1891 :

DEATH-RATES, ACCORDING TO CAUSE AND DENSITY OF POPULATION.

Houses containing	Death-rate from		
	Diarrhœal diseases.	Phthisis.	Other tuberculous diseases.
Less than 20 tenants..... ...	1.97	3.38	.53
20 and less than 40.	1.89	2.86	.51
40 and less than 60.....	2.41	2.71	.61
60 and less than 80.....	2.57	2.41	.66
80 and less than 100	2.62	2.37	.61
100 and over.....	2.00	1.95	.65

This has been attributed to the fact that the larger houses are, as a rule, newer ones, are better built, with better facilities for light and ventilation, and, as the rents are generally higher, are occupied by people slightly higher in the social scale, or at least, possessed of more means, and therefore able to live in more comfort, than those who live in the smaller houses. The whole matter, however, needs further investigation.

Much the same result has been noticed in new buildings of this kind in London, where the Peabody and Artisan's Block buildings are occupied by a large population on a small area. In the Peabody buildings there were in 1884, 18,453 persons living in 10,144 rooms. The death-rate, corrected for hospital deaths, was 19.1 per 1,000, or 1.2 below the general death-rate of London. The birth-rate, on the contrary, was high, being 44.6 per 1,000, this of itself showing that the houses are occupied by young and vigorous people at the healthy ages. The mortality among infants, the most sensitive test, was only 138.7 per 1,000 births, 13.7 below the average for London.

The higher death-rates which are found in the denser populations are not, of course, entirely due to the crowding *per se*—*i.e.*, to the vitiation of the atmosphere by the breath and the bodily emanations of the population, but to a variety of other causes also. The densest populations are, as a rule, also the poorest, and all the evil effects of poverty exist among them. They have unwholesome and insufficient food, are often badly housed, exposed to winter cold and summer heat, in an unusual degree, by reason of lack of fuel and of suitable clothing, and generally have long hours of labor with little leisure, and few means of gratifying the social instincts even when they are at leisure. Owing to the hopeless feeling engendered by their surroundings they are, more often than not, filthy in person and in their immediate belongings, and even those who have the scantiest means are prone to endeavor to mitigate the horrors of their life by the tem-

porary oblivion which intoxication brings to them. Besides all these causes, the close proximity of others under the same roof renders the propagation of contagious and infectious diseases much more certain, more extensive, and more difficult of control.

Effect of Sanitation on Mortality.—The death-rate, as before shown, has decreased during the past twenty years, in almost all the civilized countries of the world, and that this decrease is due to the great attention everywhere paid to improving the sanitary condition of communities admits of no doubt whatever. For example, in Vienna, the deaths from typhoid fever averaged 700 to 800 per annum from 1851 to 1873. In the latter year arrangements were completed for a new water-supply, and a new system of sewerage was completed. The number of deaths from typhoid fever then began to decrease as follows: In 1873, 742; 1875, 502; in 1878, 200; in 1880, 152; in 1884, 95. In Munich, the sewerage system was completed in 1880. The average annual mortality from typhoid fever from 1866 to 1880 was 594, and from 1881 to 1888 only 104, notwithstanding a marked increase in the size of the city. In England, twenty-eight towns, with a combined population of 8,752,354, gave up the privy-vault system and substituted sewers, between 1860 and 1870. The mortality from typhoid fever in these towns shows the following changes:

DEATHS IN 100,000 INHABITANTS.

1850–1860 (before the construction of sewers)	91
1860–1870 (during the construction of sewers)	89
1870–1880 (after the construction of sewers)	49
1881	27
1884	29

The following table is extracted from a much more elaborate one contained in the reports of Mr. Simon, medical officer of the Privy Council, showing the effect of new drainage-works in England. The original figures were prepared by Dr. Buchanan, in 1867:

Towns.	Periods for which death-rates are compared.		General death-rate.		Typhoid fever.		Phthisis.	
	Before the works.	After the works.	Before	After.	Before	After.	Before	After.
Banbury	1845-53	1857-64	23.4	20 5	1.6	.85	2.67	1.57
Cardiff	1847-54	1859-66	33.2	22.6	1.75	1.05	3.47	2.87
Croydon	1845-50	1857-64	23 7	19.0	1.5	.55	....	....
Dover	1843-53	1857-65	22.6	20.9	1.4	.9	2.65	2.13
Leicester	1845-51	1862-64	26.4	25.2	1.5	.75	4.34	2.93
Macclesfield	1845-52	1857-64	29.8	23.7	1.43	.85	5.15	3.54
Merthyr	1845-55	1862-65	33.2	26.2	2.13	.87	3.87	3.44
Rugby	1845-51	1855-64	19.1	18.6	1.00	.90	2.85	1.63
Salisbury	1844-52	1857-64	27.5	21.9	.75	.18	4.44	2.27
Stratford	1845-53	1860-64	21.7	20.2	1.25	.40	2.67	2.65
Warwick	1845-55	1859-64	22.7	21.0	1.90	.90	4.00	3.24

A remarkable illustration of the effect of sanitation upon the public health is afforded by the English reports, which have been accurately kept since 1838, when the office of the Registrar-General was established. The death-rate, in spite of all that had been done, although slightly lowered on the whole, was not as much influenced by the sanitary improvements from year to year as had been anticipated or desired, until the new Sanitary Acts were passed in 1874, when a decline in the death-rate began almost immediately. At first this decline was supposed to be temporary, like previous declines, but it has kept steadily on, until at present the death-rate for all England is very near to the point which Dr. Farr fixed upon as the ideal death-rate for healthy communities, viz., 17 per 1,000. The following table will make this clear:

DEATH-RATES PER 1,000 LIVING IN ENGLAND BY PERIODS OF FIVE YEARS.

Years.	Death-rate.	Years.	Death-rate.	Years.	Death-rate.
1838-40	22.4	1856-60	21.8	1876-80	20.8
1841-45	21.4	1861-65	22.6	1881-85	19.3
1846-50	23.3	1866-70	22.4		
1851-55	22.7	1871-75	22.0		

In order to show how precisely the decline indicated in this table coincided with the passage of the Sanitary Acts, the death-rates are given below for single years, before and after 1875:

Years.	Death-rate.	Years.	Death-rate.	Years.	Death-rate.
1870	22.9	1877	20.3	1884	19.5
1871	22.6	1878	21.6	1885	19.0
1872	21.3	1879	20.7	1886	19.3
1873	21.0	1880	20.5	1887	18.8
1874	22.2	1881	18.9	1888	17.8
1875	22.7	1882	19.6	1889	17.9
1876	20.9	1883	19.5		

It is a common practice in the United States to estimate the improvement or decline of the sanitary condition of a community by the proportion which the deaths of children under five years of age bear to the total number of deaths. While this may, under some circumstances, afford a fair test for comparing the health of the same town for successive years, it can only be trusted where the age-constitution of the population remains practically the same through the series of years for which the comparison is made. The following table of this kind has been prepared for New York City:

Year.	Percentage of total deaths.		Year.	Percentage of total deaths.	
	Under 5 years.	5 years and over.		Under 5 years.	5 years and over.
1866	47.25	52.75	1879	45.08	54.92
1867	52.90	47.10	1880	45.87	54.13
1868	52.50	47.50	1881	45.92	54.08
1869	51.09	48.91	1882	46.20	53.80
1870	49.06	50.94	1883	40.74	59.26
1871	48.08	51.92	1884	43.59	56.41
1872	49.58	50.42	1885	42.79	57.21
1873	48.76	51.24	1886	43.16	56.84
1874	48.58	51.42	1887	43.06	56.94
1875	48 35	51.65	1888	43.21	56.79
1876	48.74	51.26	1889	43.23	56.77
1877	46.97	53 03	1890	40.66	59.34
1878	45.95	54 05	1891	41.74	58.26

It is evident, by inspection of this table, that the percentage of deaths under five years of age cannot be looked upon as a death-rate, or as resembling a death-rate in any way, for the percentage of deaths of persons five years of age and over increases in precisely the same ratio as that of the children decreases, so that if the latter were to be looked upon as indicating more salubrious conditions for the children, the former would have to be looked upon as indicating more unhealthful conditions for older people. It is also evident that any great change in the age-constitution of the population would change these percentages without really indicating any change at all in the sanitary conditions under which the population was living. And these changes in age-distribution are precisely what New York City is especially liable to on account of the disturbing effect of immigration, which in some years injects into her population a considerable mass of people over five years of age, and comparatively few children under that age, so that the percentage of deaths of children under five, upon the total, might in any year be suddenly lowered, as it was, for instance, in 1883 (the year the Brooklyn Bridge was opened, when there was probably quite an exodus of infants with their parents to Brooklyn), without indicating any change in sanitary conditions.

A better way to use the infant deaths as a test of sanitary condition is to calculate the death-rate upon the total number living under five years of age. In populations where immigration is not so much of a disturbing factor as here, this can be done. But in New York City, on account of this factor, the age-distribution of the population cannot be calculated for the inter-censal periods with

any degree of accuracy. A comparison of London and New York in this respect will illustrate this.

LONDON.

Population by census.

	Total.	Under five years.	Percentage of persons under five years of age on total.
1851	2,362,236	293,562	12.43
1861	2,803,989	362,296	12.92
1871	3,254,260	423,629	12.99
1881	3,816,483	497,044	13.02
NEW YORK.			
1865	726,386	95,020	13.08
1870	942,292	111,205	11.80
1875	1,041,886	128,162	12.30
1880	1,206,299	140,327	11.63

While the ratio in London remains almost stationary, that of New York shows very plainly the effect of adult immigration. A better method still is the one adopted pretty generally in Europe, and that is, to compare the deaths of children under one year of age with the total number of births for the year, as so many deaths per 1,000 births. The mortality under five years of age, in any case, is mostly of children under one year, *e.g.*, in New York City in 1891, out of 18,224 deaths of children under five years of age, 11,241, about sixty per cent., were under one year, and 3,523 more were between one and two, making together over eighty per cent. of the whole under two years of age. Therefore, in taking the deaths of children under one year, we are making use of a much more sensitive test than if we take all those under five; and in comparing them with the births we have a positive number for the comparison every year, instead of the uncertain number obtained by computation for the inter-censal years. This method, however, can only be used where the registration of births is complete, and is, therefore, out of the question at the present time, in this country.

The following table allows of a comparison between the two methods most in use for estimating the mortality of infants.

DEATH-RATES IN ENGLAND PER 1,000 LIVING, AND PER 1,000 BIRTHS, FOR TEN YEARS.

Year.	Children under five. Deaths per 1,000 living.		Children under one year. Deaths per 1,000 births.
	Males.	Females.	
1881	56.4	47.9	130
1882	62.5	53 6	141
1883	59.3	49.7	137
1884	62.3	52.8	147
1885	57.5	48.4	138
1886	60.3	50.9	149
1887	57.8	48.9	145
1888	52.7	44.0	136
1889	55.6	47.0	144

Another method, which is sometimes used for comparing the sanitary condition of one place with another, or of the same place year by year, is to fix upon some disease whose prevalence is believed to indicate faulty sanitary conditions, and compare the deaths from that disease with the total number of deaths. But this furnishes an altogether unstable basis for comparison, for it is an attempt to fix upon ratios between events, both of which fluctuate, sometimes violently. Dr. Ransome gives the following illustration of the uncertainty and untrustworthiness of comparisons made in this way. Suppose two towns, each containing a population of 100,000. Suppose that in A there are 2,000 deaths a year, making a death-rate of 20 in 1,000, and in B there are 4,000 deaths a year, making a death-rate of 40 per 1,000. Suppose that in A there are 500 deaths a year from phthisis, and in B 1,000 deaths from phthisis. Now, if the comparison is made between the deaths from phthisis and the total number of deaths, it is the same in both cases, viz.: twenty-five per cent. of the total number of deaths, and in so far as this test goes, the sanitary condition of B is as good as that of A. But as a matter of fact, the death-rate of B is twice that of A, and the deaths from phthisis in B are 10 per 1,000, while in A they are only 5 per 1,000.

Sickness-rates.—For the purpose of comparing the results of treatment, and of comparing one epidemic with another, ratios are computed between the number of deaths and the number of persons attacked. In making such comparisons the total number of cases should always be given, so that others can judge for themselves whether they are sufficiently numerous to justify rigid conclusions. For in this respect, as in most others, there is danger of drawing conclusions from an insufficient number of data. Moreover, a bare comparison of deaths with the number of cases of sickness can give no valuable information, because the mortality may vary so much with the age or sex of the person attacked, and also at different times. It is well established that some epidemics of a disease are much more fatal than others of the same disease, as in the recent successive epidemics of influenza throughout the world. Also, in the same epidemic, the mortality varies greatly, the disease generally being quite fatal at the commencement, increasing in virulence for a certain time, and then growing less and less fatal during the decline. Dr. Farr, in his second annual report, made a series of calculations relating to the epidemic of small-pox in England in 1838 and 1839, which show this in a singular manner. The deaths are given below by quarters (periods of three months).

DEATHS OBSERVED IN THE DECLINE OF EPIDEMIC.

1	2	3	4	5	6	7
4,365	4,087	3,767	3,416	2,743	2,019	1,631

DEATHS IN A REGULAR SERIES.

1	2	3	4	5	6	7
4,364	4,147	3,767	3,272	2,716	2,156	1,635

The mortality decreased at accelerated rates; the rate of acceleration being 1.046, which may be called the constant. The decrease from one number to another is successively 5, 10, 15, 20, 26, and 32 per cent., and the rates of decrease, 1.052, 1.101. 1.152, 1.205, 1.260, 1.318. The division of 4,364 by 1.052 reduces it to 4,147, etc. The constant 1.046, by successive multiplications, will produce all the rates first given, 1.052, 1.101, etc.

The decline of the epidemic in London is shown below:

	1	2	3	4	5
Mean quarterly deaths registered. ..	1,103	959	611	240	91
Calculated series.....	1,103	967	611	278	91

The first rate of the calculated series was 1.14, and the others were obtained by multiplying 1.14 four times in succession by 1.39, the constant.

WALES AND THE WESTERN COUNTIES OF ENGLAND.

Mean quarterly	1	2	3	4	5	6	7	8
deaths registered.	1,157	813	621	489	304	194	116	81
Calculated series..	1,157	858	621	440	304	206	136	88

The first rate was 1.35; the constant, 1.023.

In the short tables just quoted, some necessary corrections have been neglected, and there are discrepancies between the actual and the calculated series. But in the following table these corrections have been made. Thus the quarterly rate of mortality by small-pox has been obtained by dividing the deaths in a quarter by the population in the middle of the quarter, and then the annual rate is obtained by taking four times the quarterly rate. But the quarters vary in length from 90 to 92 days, and to be strictly accurate, the mortality of the March quarter would have to be raised in the proportion of 90.5 to 91.25. Now, making the proper corrections on

this plan, the subjoined table was constructed for England:

	1838				1839	
	Mch. 31.	June 30.	Sept. 30.	Dec. 31.	Mch. 31.	June 30.
Annual rate of mortality (observed)	.114	.105	.096	.086	.070	.051
Ditto (calculated)	.114	.105	.096	.086	.070	.050

Here the agreement is extraordinary; the rates of decrease were 1.08, 1.09, 1.11, 1.24, and 1.39. The first three were produced by multiplying by 1.011; the two last by 1.12.

There are several ways of calculating the death-rates in hospitals, but they are all more or less unsatisfactory, because the conditions under which they are conducted differ so much that a fair comparison is almost impossible. Moreover, it is very difficult to decide with what numbers the deaths ought to be compared in order to obtain the death-rate. One method is to comparet he number of deaths with the number of occupied beds as ascertained by a census—what Dr. Newsholme calls a *bed death-rate*. This obviously takes no account of the number of times each bed may have been occupied, and a death-rate of one hundred per cent. would mean simply that there had been one death for every bed. The information thus given is of absolutely no practical value. The death-rate is sometimes calculated on the total number of admissions during the year. But this again is often misleading, for if the account is made up for each year separately, the number remaining at the end of each year will be counted twice, once in each of two successive years, being counted as admissions iu one year and as remaining over in the subsequent year. If a calculation is made for a series of years, this source of error should be carefully guarded against, as it is one into which one is very likely to fall.

A better method than this is that of Dr. Bertillon, who adds to the number at the beginning of the year one-half the sum of those admitted and those going out; but the plan which is generally agreed upon as the best for a crude death-rate for hospitals, is to compare the number of deaths with the total number of cases treated to a termination, either by discharge, transfer, or death.

A comparison of one hospital with others by means of death-rates gives rise to all sorts of false conclusions, and is practically worthless. Of course, no proper comparison can be made at all between the mortality in hospitals devoted to the treatment of special diseases, *e.g.*, it would be ridiculous to institute such a comparison between an orthopædic hospital and a cancer hospital, between an institution devoted to the treatment of venereal diseases and one for the treatment of phthisis. But a comparison between the death-rates of general hospitals is almost as misleading; for, entirely independent of the sanitary condition of the institutions, or the skill of the treatment to which patients are subjected, much depends upon the age and sex of the patients themselves. For instance, a large proportion of children, among whom scarlet fever became prevalent, might raise a death-rate materially. In typhus fever, the difference in the mortality of the disease among adults, to whom the disease is very fatal, and children, who almost all recover, is well known. Then, too, the attendance of physicians or surgeons of great eminence in any particular institution is certain to attract the most desperate cases, so that, as the consulting physician in private practice is likely to have the highest death-rate among his patients, so the hospital which has the most distinguished staff, and therefore presumably the most skilful treatment, will probably have the highest death-rate.

Hospital death-rates, therefore, are not susceptible of comparative statement, unless the cases are reported in much greater detail than they are at present, or than they are likely to be for many years to come. Not only the number of patients treated should be given, but the diseases, the ages and sex, and the duration of treatment in days.

The general death-rate of a population being, as already shown, a very unsatisfactory means of comparing the sanitary condition of any place or country with another, various other methods have been devised, which must be briefly mentioned.

Mean Age at Death.—This is obtained by dividing the sum of the ages at death by the number of deaths. For example, if out of 100 persons, 20 die at 5 years of age, 30 at 25, 30 at 40, and 20 at 60, the mean age at death will be obtained as follows:

$$\frac{(20 \times 5) + (30 \times 25) + (30 \times 40) + (20 \times 60)}{100} = \frac{100 + 750 + 1200 + 1200}{100} = \frac{3250}{100} = 32.5 \text{ years.}$$

This method, however, like the general death-rate, is not suitable for comparing different communities, unless the age-constitution of the two are the same. For obviously, the number who die at each age will depend upon the number living at that age. The following illustration is given by Dr. Guy. If A has 46 per cent. of its population under 20 years of age, and B has 54 per cent., then if half the inhabitants of A and B die under 20, and the mean age of these at death be assumed to be five years, and of all over 20 to be 60 years, then the mean age at death of 50 persons in A would be $= \frac{\frac{46}{2} \times 5 + \frac{54}{2} \times 60}{50} = \frac{115 + 1620}{50} = \frac{1735}{50} = 34.7$ years, and in B would be $= \frac{\frac{54}{2} \times 5 + \frac{46}{2} \times 60}{50} = \frac{135 + 1380}{50} = \frac{1515}{50} = 30.3$ years. Thus, assuming that the general death-rate of A and B is the same, the mean age at death differs by 4.4 years, owing to the different age-constitution of the population. This source of error will vitiate comparisons between different periods in the same country, and between cities and country towns, as well as different countries. The mean age at death has also been used for the purpose of comparing the healthfulness of different occupations, but in this case it is so misleading as to be almost worthless, unless the age-constitution of the masses of persons compared are the same. It would be obviously incorrect to compare the mean age at death, for instance, of bishops and other clergymen, for clergymen do not often become bishops until they reach middle life. Other instances of this fallacy have been given elsewhere.

The *probable duration of life* (*vie probable*) means the age at which any number of persons followed from birth would be reduced one-half, *i.e.*, the age at which one-half are already dead. It differs greatly from the mean age at death, and does not seem to be of any practical importance. If out of a population of 100, 10 die at 5 years of age, 10 at 15, 10 at 25, 10 at 35, 10 at 45, 10 at 55, 10 at 65, 10 at 75, 10 at 85, and 10 at 95, then the probable duration of life would be 45 years, at which age 50 of the number would have died; but the meau age at death would be:

$$\frac{50 + 150 + 250 + 350 + 450 + 550 + 650 + 750 + 850 + 950}{100} = 50 \text{ years.}$$

The *mean duration of life* (*vie moyenne*), in a stationary population, where births equal deaths and there is no immigration nor emigration, is the same as the mean age at death. But in the ordinary population, where the births do exceed the deaths, and there is more or less migration, the mean duration of life is the same as the mean after-lifetime taken at birth, or the expectation of life at birth. This figure is obtained from a life table, the method of constructing which will next be considered.

Life-tables.—The earliest life-tables were drawn up by Ulpian, the distinguished Roman lawyer, early in the

third century A.D. (Billings). They are given in the Pandects of Justinian, and were based upon the registers giving age, sex, and deaths among the population of Rome since the time of Servius Tullius, a period of about one thousand years. From these data Ulpian constructed a scale for estimating the purchase value of communities, and calculating annuities.

The earliest English life-table was constructed by the celebrated astronomer Halley, and published in 1693. It was calculated on the deaths in the city of Breslau from 1687 to 1691.

The first National life-table ever made was constructed by Dr. Price in 1783, for Sweden, and was based upon abstracts of the living and dying in Sweden during twenty-one years, arranged by quinquennial periods after the fifth year.

The first life-table used for life-insurance purposes was also constructed by Dr. Price, and is known as the Northampton table. It was used by the Equitable Office on its establishment in 1762. This table, like Halley's, was constructed from the deaths alone, taking no account of the number of the living. Such tables are only correct in a stationary population, in which the births equal the deaths, and there is no migration.

The table known as the Carlisle table was made by Mr. Milne, and based upon the observations of Dr. Heysham upon the mortality of Carlisle for the nine years 1779–1787, and two enumerations of the population made at the beginning and end of the term; the mean population amounting to 8,177 and the deaths to 1,840.

In 1834 the Equitable Assurance Society published an abstract of the facts in their possession, from which Mr. Morgan constructed a table of mortality.

The English life-tables, Nos. 1, 2, and 3, were constructed by Dr. Farr. No. 1 was based upon the census returns of population for 1841 and the recorded deaths for the same year. In order to avoid the criticism that it was based upon the statistics of too short a time, he constructed No. 2, based upon the census enumerations of 1831 and 1841, and the deaths for the seven years 1838–1844, embracing the age records of 29,810,945 persons, and the death records of 2,436,648. English life-table No. 3 was based upon the census enumerations of 1841 and 1851, and upon the deaths registered during the seventeen years 1838 to 1854, numbering 6,470,720. The results obtained by these three tables were very nearly alike.

Besides the value of a life-table, by common consent, as the only true basis of comparison between different communities as to their sanitary condition or the general vitality of the population, it is absolutely necessary as a basis for the calculation of premiums in the insurance of lives. Accordingly, most large insurance companies have their own tables, made up by their actuaries, from their own records. Being constructed in this way from the statistics gained from the observation of selected lives, they may differ to a slight extent from a table based upon the entire population, but they are generally made up after careful corrections for all possible sources of error, and the construction of them is a very laborious task.

It is necessary, for the construction of a life-table, to have the numbers of the living, with ages, and the number and ages of the dying. Theoretically, it would be advantageous to have the exact number of the living at each year of their age, and the exact ages of the dying for each year; but practically, the liability to error in any attempt to obtain such figures renders it more desirable to use mortality and census statistics, in which the population and deaths are grouped by five- or ten-year periods. It is said by Dr. Farr that "no authentic table of mortality in practical use has ever been calculated from an enumeration of deaths at every separate year of age; and no actuary has yet shown that tables can be deduced more accurately from deaths so enumerated than from quinquennial or decennial periods."

In making up life-tables certain things have to be assumed. The first suggestion on this point came from the mathematician De Moivre, who formulated what is known as De Moivre's hypothesis from the deaths at Breslau. He concluded that the numbers living decrease in an arithmetical progression, down to nothing, at the age of eighty-six, or, in other words, that of every eighty-six persons born one dies every year until all are dead. This is an understatement of the mortality toward the beginning and end of life, and is only approximately true for the middle period. It has since been assumed, with Milne, "that the number of living in any year of their age is an arithmetical mean proportional between the number that annually enter upon and that annually complete that year." It is also assumed that the deaths occurring in any year are equally distributed throughout the year. It is obvious that the number of deaths, for instance, given for two years of age, do not all occur at the precise time when the persons completed their second year, but are distributed throughout the ensuing year, while the persons are still said to be two years of age and not yet three. A slight error is involved in the assumption of equal distribution, for the deaths are much more numerous at some seasons than at others, and even as regards age, if the mortality at two is much greater than that at three there will evidently be a larger proportion of deaths in the early part of the year than in the latter part. This source of error may, however, be safely disregarded.

It will now, perhaps, be most conducive to a clear understanding of the subject if a short life-table is first given, and the method of constructing it explained in detail afterward. The following is quoted from Farr's tables by Newsholme:

ENGLISH LIFE-TABLE FOR MALES.

Age (or past lifetime) x	Annual mortality per unit at age x $= m_x$	Probability of living one year from each age $= p_x$	Number born and living at each age $= l_x$	Mean population in each year of age $l_x + \frac{1}{2} = P_x$	Years which the males at each age will live $= Q_x$	Mean after-lifetime of males of age x $= E_x$
0	.18326	.83212	511,745	468,789	20,426,138	39.91

75	.10391	.90122	75,777	72,012	491,685	6.49
85	.21966	.80208	16,877	15,151	63,030	3.73
95	.42035	.65265	833	678	1.806	2.17
105	.....	.....	4	3	5	... .

The letter x in the heading of the columns signifies *age*, *e.g.*: m_x means mortality at the age of x, l_x means *living* at the age x, etc.

The first column, or m_x, is obtained from the total number of living at each age, as returned by the census, and the total number of deaths recorded for each age. The numbers in the column are the death-rates for the respective ages, only they are death-rates per unit, instead of rates per 1,000. They are obtained by the formulas previously mentioned, viz.: death-rate $=$ $\frac{\text{total number of deaths}}{\text{total population}}$. The first number, for instance, .18326, indicates the death-rate during the first year of life, *i.e.*, 183.26 per 1,000 living, or .18326 per unit living.

The second column, or p_x, represents the probability of living one year, *i.e.*, the probability that a person who is living at the beginning of a year will live to see the end of it. The number in the first column represents the death-rate of the mean population of the year, *i.e.*, as it is there expressed, the mortality of one individual in the middle of the year. But as the deaths are assumed to be equally distributed throughout the year, the number living at the beginning of the year will evidently be greater than that living in the middle of the year by just one-half the number of deaths for the year, and the number living at the end of the year will be just so much smaller.

So if m represents the annual number of deaths, and 1 represents the unit of population living in the middle of the year, then $1+\frac{m}{2}$ will equal the number living at the beginning of the year, and $1-\frac{m}{2}$ will equal the number living at the end of the year. Now, the number living at the end of the year, divided by the number living at the beginning, will give the probability which each person at the beginning of the year has of living to the end. If 100 are living in the middle of the year, and the mortality is 4 a year, there will be 102 living at the beginning and 98 at the end of the year, and $\frac{98}{102}$ will represent the probability of living a year for each of the 102. So $p_x = \frac{1-\frac{m}{2}}{1+\frac{m}{2}} = \frac{2-m}{2+m}$. In the table, the mortality being .18326, the probability of living one year equals $\frac{2-.18326}{2+.18326} = \frac{1.81674}{2.18326} = .83212$, which is the first number in the second column.

The next column, or l_x, represents the number of persons living at the beginning of each year. In the table, the first number, 511,745 represents the number of newly-born children, and the next number, 370,358, the number who are five years old, *i.e.*, who have completed their fifth year and are beginning the sixth. The intervening years are not given in this table, for the sake of brevity, but the number for each year is obtained by multiplying the number living at the beginning of the previous year by the probability of living a year, this evidently giving the number surviving at the end of the year. That is, each successive number in the third column is obtained by multiplying l_x by p_x. Thus the number living at one year of age (which is omitted from this abbreviated table) would be obtained by multiplying 511,745 by .83212, which gives 425,833. This would be the second number in a complete life-table, and the third number would be obtained in like manner, by multiplying this one by the p_x for one year.

The fourth column contains the mean population for each year, which is obtained by taking half the sum of those living at the beginning and the end of each year. If the table were complete, each number in this column would be half the sum of the corresponding number in the column headed l_x and the one next succeeding. In the present case it is equal to $\frac{511,745+425,833}{2} = 468,789$. This is called P_x.

The fifth column, headed Q_x, *i.e.*, the quantity of life, as it might be called, at each age, represents at each age the number of years of life remaining to the persons living at that age. Each number in this column is equal to the sum of all the numbers at that and the subsequent ages in the previous column, headed P_x. The reason of this is plain. The same number of years of life are lived whether one man lives 100 years, or 100 men live one year. Now to take the example previously used, if there are 102 living at the beginning of the year and 98 at the end (*i.e.*, the beginning of the next year), on the supposition that the deaths are evenly distributed through the year, the 102 live only one-half of the year, and the 98 the other half of the year, making in the one case 51 years of life, and in the other 49, or 100 years of life together, *i.e.*, $\frac{102+98}{2} = 100$. So in the next year, the death-rate remaining the same, the number of years lived would be equal to $\frac{98+94}{2} = 96$, making the total number of years lived by the 102 living at the beginning of the first year equal to 196 at the beginning of the third year, or end of the second. But 100 and 96 represent the mean population of the first and second years respectively, and so would be in the column P_x.

The sixth column, headed E_x., *i.e.*, the expectation of life at any age, is the column for which all the other columns have been preparatory, and represents the number of years of future lifetime for each unit of the population. Each number in this column is obtained by dividing the corresponding number in the column headed Q_x by the one in the column headed l_x. For if, for instance, there are 511,745 males living at the beginning of a year, and the males at that period have a total future lifetime of 20,426,138 years, it is evident that the future lifetime of each unit, *i.e.*, the mean after-lifetime, or expectation of life at that age, will be equal to 20,426,138 divided by 511,745, which gives a quotient of 39.91.

A shorter method of constructing life-tables is given by Dr. Farr, as follows:

"The arithmetical labor involved in the construction of correct life-tables, showing the living at every year of age, is very considerable. But for a great many purposes the number surviving every five years, after the five first, and the expectations of life at those intervals, furnish quite sufficient information, *e.g.*:

"Up to the age of five years the method is the same as that already described, and it was thus found that of 50,521 boys born in Surrey, 43,637 live a year, 41,857 two years, 40,704 three years, 40,031 four years, 39,550 five years. The next point was to determine how many of the 39,550 attain the age of ten years. The living enumerated at the age five to ten were 13,588, the deaths 145; and after the proper correction the mortality m was ascertained to be .01050; so $\frac{m}{2} = .00525$ and $\frac{1-\frac{1}{2}m}{1+\frac{1}{2}m} = \frac{.99475}{1.00525} = .98955$, the probability of living *one year* at the middle of the period, or at seven and a half years of age. But it may be assumed that $\left(\frac{1-\frac{1}{2}m}{1+\frac{1}{2}m}\right)^5 = (p_5)^5 =$ the probability of living the five years from the age of five to ten; and $(.98955)^5 = .94885$; which multiplied by 39,550 gives 37,527 = the number surviving at the age of ten.

"If the calculation be continued down to 15, 20, 25, and every fifth year to the end, the following table will be obtained:

SURREY LIFE-TABLE. MALES (1841).

Age.	Living.	Quinquennial periods + ½ lm	Age.	Living.	Quinquennial periods + ½ lm
0	50,521	476,444	45	28,069	149,225
1	43,637	.....	50	25,973	121,156
2	41,857	.....	55	23,892	95,183
3	40,704	.....	60	21,459	.....
4	40,031	.....	65	18,235	.....
5	39,550	425,923	70	13,976	.....
10	37,527	386,373	75	9,836	.....
15	36,469	348,846	80	5,393	.....
20	35,338	312,377	85	2,031	.....
25	34,061	277,039	90	290	.....
30	32,742	242,978	95	58	.....
35	31,189	210,236	100	11	.....
40	29,822	179,047	105	2	.....

"Add up the column headed living to the number 39,550 (against the age five years), and the sum will be the number of five years—of *lustres*—which the 39,550 persons will live $+\frac{39.550}{2} = 19.775$. Subtract, therefore, 19,775 from 425,923, and 406,148 will remain; which, divided by 39,550, gives for quotient 10.269 *lustres* as the expectation of life at that age. A lustre is five years; consequently the expectation of life in years is five times 10.269, or 51.3 years. If 425,923 be divided by 39,550, the quotient will be 10,769; and $10,769 - .5 = 10,269$, the same result as before.

"A life-table still shorter may be constructed by taking intervals of ten years, and using the formula $\left(\frac{1-\frac{1}{2}m}{1+\frac{1}{2}m}\right)^c$.

The errors in the calculation of the expectation of life from the living at every tenth year can be corrected. They are always of the same nature, causing an excess, between 10 and 50, from .1 to .2 or .3 of a year."

A still shorter method was described by Mr. Noel A. Humphreys, in a paper read before the Statistical Society, in April, 1883, on "The Recent Decline in the English Death-rate." As an illustration, he took the mean annual death-rate in the seventeen years 1838–54, and in the five years 1876–80, at each of the twelve gronps of ages given by the Registrar-General in his annual reports. Having then calculated the rate of increase or decrease of the relative rates of the two periods at each group of ages, he started with the annual mortality for males and females, respectively, in each year of life, as given by Dr. Farr's English life-table, No. 3, and raised or lowered these in accordance with the increased or decreased mean mortality prevailing during 1876–80 in the several gronps of ages. There is an obvious defect in this series of corrected annual rates of mortality, which is pointed ont by Mr. Humphreys himself. This lies in the "assnmption that the changes in the proportions of decrease in the mean rates of succeeding age-periods, took place suddenly at the commencement of each period instead of coming gradually into operation, as was certainly the case." But for the purpose of estimating the mean after-lifetime, this method is sufficiently accurate, and forms a comparatively easy method of constructing local life-tables (Newsholme).

This was the method used in constructing the life-tables for States and cities for the United States census report of 1880, some of which will be found qnoted below.

The table on next column (also from Newsholme) shows the expectation of life (mean after-lifetime) according to various well-known life-tables.

Life-tables based upon American experience will be found in the article on Mortality, in Vol. V. of this work, pp. 25, 26. An inspection of these tables will show that, while the progress of sanitary reform has resulted in an appreciable diminution of infant mortality, there has been an increase of the mortality among adults. A comparison of English life-table, No. 3, with the more recent one of Dr. Ogle, shows a considerably increased expectation of life up to fifteen years of age, and after that a decreased one. This is due partly, perhaps chiefly, to the saving

Age.	De Moivre's hypothesis.	Northampton table.	Carlisle table.	English life-table, No. 1.	English table, No. 2.	English table, No. 3.		New English life-table (Dr. Ogle's).

in infancy and childhood of many lives of delicate and weakly persons, who succumb to the stress of adult life more easily and in greater numbers than when the adults were the result of a more rigorous natural selection in childhood. The great increase of town population of late years has probably also had much to do with this increased mortality of adults, for the death-rates of cities are always higher than those of rural districts.

It should be kept in mind that the expectation of life, as given in life-tables, is merely an average made up from data derived from a large number of persons, and has no relation to any single individual. It does not imply that any single person may expect to live a certain number of years, for some will live much longer and others die much earlier.

The following table, taken from the United States census report of 1880, shows the expectation of life in many cities and some States in this country:

Ages.	Baltimore.		Boston.	Brooklyn.	Chicago.	Cincinnati.	New Orleans.	New York.	Philadelphia.	San Francisco.	District of Columbia.		Massachusetts.	New Jersey.
	White.	Colored.									White.	Colored.		
0	38.18	23.26	38.08	38.61	39.70	40.44	25.56	35.02	41.93	41.32	42.36	25.25	44.64	46.82
1	46.04	35.32	46.65	45.94	47.30	48.44	36.58	43.70	49.54	48 68	49.34	36.32	51.19	53.44
2	49.80	41.91	49.84	49.66	50.96	51.26	40.11	47.94	51.56	49 94	51.81	42.29	53 18	55.05
3	51.05	43.66	50.52	50.66	52.00	52.16	41.25	48.90	52.24	50.16	52.21	44.26	53.74	55.54
4	51.58	44.07	50.90	50.97	52.74	52.32	41.08	49.20	52.30	50.03	52.20	44.58	53.90	55.48
5	51.72	44.32	50.86	51 02	52.90	52.06	40.76	49.14	52.02	49.54	51.85	44.48	53.80	55.18
10	49.66	42.40	47.96	48.62	51.12	49.11	37.50	45.91	48.56	45.76	48.71	42.13	50.97	52.04
15	45.46	39.42	43.68	44.42	47.10	44.78	33.75	41.62	44.30	41.38	44.38	38.44	46.86	47.88
20	41.50	36.62	40.14	40.36	43.20	40.76	30.63	37.64	40.37	37.42	40.42	35 34	42.29	43.90
25	38.06	33.68	36.99	36.94	39.52	37.20	29.02	34.20	37.01	34.00	36.72	32.76	40.12	40.48
35	31.42	27.62	30.68	30.45	32.53	30.41	24.95	28.02	30.68	27.78	30.54	27.68	33.54	33.54
45	24.67	21.74	24.04	24.01	25.58	23.96	20.04	22.14	24.24	21.92	24.19	21.58	26.72	26.47
55	17.86	16.10	17.76	17.71	18.70	17.58	15.52	16.34	17.98	16.50	17.92	16.22	19.72	19.56
65	12.17	10.72	12.22	12.21	12.68	11.75	10.90	11.19	12.26	11.36	12.10	11.18	13.52	13.44
75	8.32	7.02	7.94	8.20	8.31	7.77	7.07	7.70	8.12	7.51	7.56	7.22	8.72	8.57
85	5.98	5.72	6.33	5.69	6.28	5.71	5.85	5.60	5.68	6.96	5.54	5.52	5.97	6.20

The figures given for each age are the arithmetical means of the males and females in each case. The table was made up from the deaths for one year in every instance excepting the District of Columbia, where the deaths for the three years 1879–81 were used.

In cases where a life-table is obtainable, the *formula of Willich* gives approximate results for ages between 25 and 75, as follows: if x = expectation of life and a = present age, then $x = \frac{2}{3}(80 - a)$. Thus, at the age of 40 years, the expectation of life according to this formula would be $\frac{2}{3}(80-40) = 26.7$ years. By the English life-table, No. 3, the expectation of life for this age is 26.06 years for males, and 27.34 for females.

Dr. Farr gives another formula, by means of which an approximation to the expectation of life at birth may be obtained, when the birth- and death-rates are known.

If b = birth-rate and d = death-rate per unit of population, then the expectation of life $= \left(\frac{2}{3} \times \frac{1}{d}\right) + \left(\frac{1}{3} \times \frac{1}{b}\right)$

Thus in the decennium 1871–80, the birth-rate was 35.45

per 1,000, = .03545 per unit, and the death-rate was 21.4 per 1,000 = .0214 per unit. Then the expectation of life $=\left(\frac{2}{3}\times\frac{1}{.0214}\right)+\left(\frac{1}{3}\times\frac{1}{.03545}\right)=40.55$ years. By the English life-table, No. 3, the expectation of life at birth for males was 39.91, and for females 41.85, the arithmetical mean being 40.88.

The *mean duration of life* is the same as the mean after-lifetime (expectation of life) added to any age. Thus, at birth, the mean duration is the same as the mean after-lifetime. At twenty years it equals twenty plus the mean after-lifetime. Thus by the English life-table, No. 3, the mean duration of life for males would be, at birth, 39.91 years, and at 20 years of age it would be 20 + 39.48 = 59.48 years.

Dr. Farr gives the following illustration of the untrustworthiness of the mean age at death as a test of the duration of life :

	Mortality, or 1 death.	Mean age at death.	Mean after-lifetime, or, expectation of life.
England, 1841.	In 46 living.	29 years.	41 years.
France, 1841.	In 42 living.	34 years.	40 years.
Sweden, 1841.	In 41 living.	31 years.	39 years.

It will be seen that, although the mean age at death was lowest in England, the rate of mortality was also the lowest. This is owing to the great excess of young persons in the population of England as compared with that of France.

One more method of estimating the vitality of a community has been suggested by Mr. Neison, viz., to divide the number of living at any age by the number dying at that age. The result he calls the *specific intensity* at that age. Thus, out of 100,000 males born, 76,504 survive at the age of 40 years, and 927 of this number die during the year. Then the specific intensity at the age of 40 $=\frac{76,504}{927}=82.528$.

Sources of Error in Dealing with Statistics.—Many ways have already been mentioned in connection with the various subjects treated of in this article, in which fallacious conclusions may be drawn from statistics that have been improperly collected or handled, and it is not necessary to recapitulate them here. But there are a few sources of fallacy that have been temporarily passed by or insufficiently dealt with, which should be mentioned before the article is brought to a close.

1. *The Data may be too Few in Number to Justify any Trustworthy Conclusion.*—It must be always kept in mind that generalizations from insufficient data are worse than useless, because they are misleading. It is a well-known mathematical principle that the relative values of two or more series are as the square roots of the number of observations, so that by increasing the number of observations in any inquiry, the accuracy increases as the square root of the number. Absolute truth cannot be obtained by any number of observations, but the limits of error may be so reduced that the variation either way may be practically disregarded, being so small. *Poisson's formula* gives us the means of ascertaining the limits of error in any case. It is as follows : Let M = the total number of cases recorded, and m = the number in one group, and n = the number in another group, both groups making up the total number, so that $m + n = M$. Then the proportion of each group to the total will be expressed by $\frac{m}{M}$ and $\frac{n}{M}$, and the extent of the variation, or the limits of possible error, will be expressed by the formula $\frac{m}{M}+2\sqrt{\frac{2m\times n}{M^3}}$ and $\frac{m}{M}-2\sqrt{\frac{2m\times n}{M^3}}$. It is plain that the larger the value of M the less will be the value of $2\sqrt{\frac{2mn}{M^3}}$, and therefore the less will be the variation from $\frac{m}{M}$.

Thus (to use Newsholme's illustration), if out of 10 cases of cholera, 7 recover, how near is this to the true average of recoveries. The probability of recovery is $\frac{7}{10}$ and of dying $\frac{3}{10}$. According to Poisson's formula the possible error will be :

$$2\sqrt{\frac{2m\times n}{M^3}}=2\sqrt{\frac{2\times7\times3}{10^3}}=2\sqrt{\frac{42}{1,000}}=.4098.$$

Thus the possible error is as .4098 to unity. Now, what would be the possible variation in 100,000 cases ?

The average, as given, would be 70,000 recoveries out of the 100,000 cases, and the possible error is 40,980 ; therefore the number of recoveries may range between 110,980 and 29,020 (an absurdity, showing that the number of cases is too small to base any conclusion upon). Now, if 100 cases be collected, out of which 70 recover, the proportion is the same, the only difference being in the larger number of observations ; but by Poisson's formula the error is only .13 to unity, or 13,000 in 100,000 cases, so that the range of recoveries on that basis would be between 83,000 and 57,000 cases. If 1,000 observations are made with the same proportion of recoveries, *i.e.*, 700, the error, according to the formula, would be only .04, *i.e.*, 4,000 in 100,000 cases, and the range of recoveries would be between 74,000 and 66,000. And so the possible error constantly decreases, until, after the number of observations rises into tens of thousands, it may be altogether disregarded. The following table shows this clearly :

Total number of cases.	Number of recoveries.	Possible number of recoveries in 100,000 cases, by Poisson's formula.
10	7	29,020 or 110,980
100	70	57,000 or 83,000
1,000	700	66,000 or 74,000
10,000	7,000	68,700 or 71,300
100,000	70,000	69,600 or 70,400
1,000,000	700,000	69,870 or 70,130

It is evident from this table that the variation is so slight after 100,000 is reached that the collection of additional facts would be useless labor.

2. *Data should be collected on a uniform plan*, in order to make them strictly comparable. In summing up results of treatment, for example, or the fatality of the same disease in different places, attention should be paid to the fact that the mortality of a disease usually varies in the beginning, culmination, and decline of an epidemic, and care should be taken to make comparisons accordingly.

3. *Death-rates or birth-rates should never* be combined or compounded. For instance, if A, containing a population of 100,000, has a death-rate of 30 per 1,000, and B, with a population of 50,000, has a death-rate of 20 per 1,000, the common death-rate of the two places is not to be obtained by halving the sum of these rates, *i.e.*, $\frac{20+30}{2}=25$. The death-rate of the two cities taken together would not be 25 per 1,000, for the death-rate of A gives 3,000 deaths, and that of B gives 1,000 deaths, so that both places together have 4,000 deaths in a population of 150,000, giving a death-rate of 26.67 per 1,000, instead of 25.

4. *Deaths for one year should not be compared with those of another without allowing for increase of population ;* this allowance may be made either by using death-rates instead of deaths, or in the following manner :

The deaths from measles during the year 1890 were 408. How does this number compare with the annual average of deaths from this disease for the past ten years ?

The mean population of the ten years, found by adding together the populations for each year and dividing the sum by ten, was 1,388,737. The population in 1890 was 1,631,232. The average annual number of deaths from measles for the same ten years was 653.1. This number must therefore be increased, in order to compare it with the number for 1890, by the ratio expressed by $\frac{1,631,232}{1,388,737} = 1.175$. $653.1 \times 1.175 = 767$, which therefore represents the proper number for comparison with the deaths for 1890. So with whooping-cough. Annual average of deaths for 10 years = 451.6, and this multiplied by 1.175 gives 531 as the corrected average, to be compared with the deaths for 1890, viz., 487.

In conclusion, too much stress cannot be laid, in statistical investigations, upon a strict adherence to the rules formulated by Quetelet, the distinguished Belgian statistician, viz.:

1. Never have preconceived ideas as to what the figures are to prove.
2. Never reject a number that seems contrary to what you might expect merely because it departs a good deal from the apparent average.
3. Be careful to weigh and record *all* the possible causes of an event, and do not attribute to one what is really the result of the combination of several.
4. Never compare data which have nothing in common.

BIBLIOGRAPHY.

The following works are the most important ones for the library of the physician:

Vital Statistics. A memorial volume of selections from the reports and writings of William Farr, M.D., D.C.L., C.B., F.R.S., late Superintendent of the Statistical Department of the Registrar-General's office, England. Edited for the Sanitary Institute of Great Britain by Noel A. Humphreys. Edward Stanford, 55 Charing Cross, S.W., London, 1885. This book is a perfect mine of information, and indispensable to one interested in the subject.

The Elements of Vital Statistics, by Arthur Newsholme, M.D., London. Swan, Sonnenschein & Co., Paternoster Square, 1889. A useful elementary book with plain explanations, but many errors of proof-reading, especially in tables and formulæ. A good practical book, however, of which much use has been made in the preparation of this article. Contains a considerable bibliography.

On Vital and Medical Statistics. The Cartwright Lectures for 1889, by John S. Billings, M.D., U. S. A., published in the *Medical Record* of New York, on November 30, December 7, and December 14, 1889. Especially instructive to physicians, as dealing with medical and hospital statistics, in addition to much matter on vital statistics. Also contains a good bibliography.

Roger S. Tracy.

VOMITING OF PREGNANCY. By way of introduction it may be assumed that no more common source of discomfort, distress, and even danger, besets the condition of pregnancy than the symptom which serves as the subject of this article. It may be asserted also, that very few who have not experienced it have any adequate idea of how distressing it may, and often does, become. It is doubtless a fact that the nausea accompanying, or at times taking the place of, the actual vomiting, is of such intensity, is of such a sickening and depressing character, is so much worse than the ordinary and commonplace nausea due to other causes, as to be to many the hardest to bear of all the trying experiences of the process of maternity.

At other times, it must be admitted, the vomiting is easy, accompanied by little, if any, nausea, and it is a noticeable fact that even in some cases in which vomiting has been frequent and persistent for months, the patients have held their flesh and strength to a wonderful degree. In these latter cases the body must hold its own with a very meagre supply of food, for to a casual observer it would appear that none is retained.

It has been customary to draw a line of demarcation between the slight and the severe cases, or between those which are rebellious to treatment and threaten life, and those which do not. The former have been called the "physiological" or "simple" vomiting of pregnancy; the latter the "pernicious," or incoercible," or "uncontrollable" vomiting of pregnancy. The correctness of these descriptive terms will be called in question elsewhere.

On the other hand, Dr. Graily Hewitt has very properly pointed out the important distinction which exists between the vomiting *of* pregnancy and the vomiting *during* pregnancy, the latter being merely an accidental occurrence in the course of pregnancy, while the former is a direct result from the fact of pregnancy.

As regards the history of this troublesome complication, it is probably the history of the human race, for from the nature of the case it must have been a frequent symptom during pregnancy at a very early period in the history of the world. What Hippocrates and other ancient worthies have to say upon the matter, however, is of far less importance than the fact that so many men in the present day show plainly by their writings how little they understand either the cause or the treatment of the trouble. The very multiplicity of theories as to the cause, and of remedies for working a cure, serves as a sufficient commentary upon the unsettled state of medical opinion upon one of the most common and important symptoms which the physician is called upon to treat. It does not seem right that so simple and every-day an experience as the vomiting of pregnancy should remain at the present day a matter of mystery, and that its treatment should continue so unsatisfactory, uncertain, and often futile. The writer believes that most, if not all cases, may be explained according to a very simple theory, and his experience demonstrates that treatment along that same line may be confidently expected to give prompt and complete relief in the vast majority of cases.

SYMPTOMS.—The most common form of this complaint is the occurrence of one or more attacks of vomiting directly after rising from bed in the morning. This may end the attack for the day, or the vomiting may recur during breakfast as well as at intervals throughout the day. So frequent is this experience on rising, that the affection has come to be universally known as "morning sickness."

At times vomiting is absent, but the patient experiences attacks of nausea instead. Either the nausea or the vomiting may begin before rising, at times even awaking the patient from her sleep, and may then recur as above stated.

In the severer forms of pregnancy vomiting every attempt to take food is followed by fresh paroxysms, and indeed, not infrequently, vomiting is well-nigh constant, irrespective of anything which is taken into the stomach. The symptoms may be so urgent that sleep is prevented, nutrition wholly fails, loss of flesh and strength are rapid, elevation of temperature, small and rapid pulse, delirium and death supervene, all in the course of a few weeks.

It has been customary to divide these severe cases, commonly known as the pernicious vomiting of pregnancy, into three stages. During the first stage the symptoms develop with more or less rapidity, as a rule giving no indication of the gravity of the situation which is to follow until, after a period varying from a few days to several weeks, the vomiting becomes so frequent and so urgent as materially to affect the patient's strength. The threatening aspect of the case now visibly augments from day to day. Nothing whatever is retained upon the stomach, and, in default of food or drink, vomiting of mucus, bile, and even blood, continues at short intervals.

No one can now overlook the serious nature of the complication. Suffering and anxiety are plainly depicted in the patient's face, the pulse has already become markedly accelerated, and then, with the advent of fever, is ushered in the second stage.

In this stage the temperature remains persistently above 100° F., the pulse varies from 100 to 140 per minute, the skin is hot and dry except that in some cases the extremities remain cold and clammy. Thirst is a prominent symptom, the mouth is parched and dry, the tongue may be cracked, and sordes may appear upon the teeth. Ptyalism and jaundice are commonly present. The urine is scanty, often albuminous and tinged with bile. As a rule, diarrhœa exists.

With the onset of the third stage most of these symptoms abate, the patient being able once more to take and

retain small amounts of food. The friends and even the physician may be deceived, thinking convalescence about to be established, while in fact this is merely the period of grave disturbance of the nerve-centres preceding death. Delirium is present, with loss of one or more of the special senses. Neuralgic pains are commonly present. The pulse remains between 120 and 140. Coma gradually supervenes and continues until death.

The period of pregnancy at which nausea or vomiting most frequently occurs is during the first six or eight weeks, though they may appear at any time up to delivery. One case is reported in which the patient was married on Monday, began vomiting on the following Saturday, and was delivered normally at such a time as to establish the fact that conception immediately followed marriage. It is probable, however, that discomfort is first noticed, in the majority of cases, somewhere near the end of the first month of pregnancy. Beginning as a slight nausea on rising in the morning, or at the breakfast-table, it may go on to the serious train of symptoms described above, or after a few days may wholly disappear. Usually the experience is one of annoyance rather than of actual suffering, and rarely continues after the fourth month.

Diagnosis.—The points involved in the diagnosis are, *first*, to determine the fact of pregnancy; *second*, to decide whether the vomiting is due to the pregnancy or is simply incidental to it—in other words, whether we have to deal with the "vomiting *of* pregnancy" or the "vomiting *during* pregnancy;" and perhaps I may be permitted to add, *third*, to ascertain the local cause of the vomiting.

It is by no means easy to establish the fact of pregnancy at an early stage, and indeed it is often impossible. Until after the first catamenial period has passed it must be chiefly a matter of inference, based upon the opportunity which has been afforded for pregnancy to occur, and upon the possibility or otherwise of the vomiting being due to other causes. As soon as one menstrual period has passed, or when other signs of pregnancy have been discovered, the diagnosis may be made to rest upon a surer basis.

The difficulties in the way of deciding the second point in diagnosis are usually less marked. The peculiar characteristics of pregnancy vomiting are usually sufficiently well marked; yet in some cases it may be necessary to avail one's self of an eliminative diagnosis, making careful examination for disease of stomach, liver, kidney, or other organ which might be productive of the symptoms, and failing to find such cause the diagnosis must rest upon the pregnancy as responsible.

The diagnosis of the abnormal conditions which serve as a cause for the vomiting will be considered under the next heading.

Cause.—Here we reach the great point of difference which exists between observers, and yet the point upon which it is most important that definite and correct views should exist, for upon it must rest the most successful treatment. It has been customary to attribute the vomiting to a reflex irritation proceeding in some mysterious way from the developing ovum, but more stress has commonly been laid upon the condition of the patient, whether as concerning her stomach or her nervous system, which made this irritation potent for evil, than upon the source of irritation itself. Moreover, as regards the nature of this irritation, men have held, and hold to-day, most divergent views, though it is coming to be admitted more and more generally that its origin is to be found in some abnormal pelvic condition.

My own preference is to consider that a number of causes may operate in different cases, or even in the same case, to produce the symptoms, and these causes should be classified as predisposing and exciting.

As to the predisposing causes, the chief is undoubtedly that state of exalted nervous sensibility which shows itself in so many and in such unmistakable ways during pregnancy. It is a matter of universal observation that trifling emotions, whether of fright, grief, annoyance, or otherwise, produce in the pregnant woman results far surpassing those which she would ordinarily experience. Similarly, it is doubtless true that conditions giving rise to irritation of sensory nerve-fibres may give rise to correspondingly exaggerated results in the way of reflex phenomena.

Undoubtedly an important factor in this connection lies hidden in racial conditions. In no other way can we adequately explain the fact that Carl Braun, in his enormous experience, has never met with a fatal result, nor even with a case sufficiently serious to require induced abortion, while in France, England, and America a fatal termination is far from being a rarity. Hirst, in the recently published "System of Therapeutics," shows a mortality of 95 in 239 cases reported.

Other factors may possibly be found in the hydræmic condition of the blood; the condition of fear, or at least the state of introspection and anticipation in which so many newly pregnant women find themselves; the various functional perversions of taste, smell, appetite, and digestion; and lastly, and more generally, in the presence of gastric catarrh in more or less marked degree.

Far more important, however, are the exciting causes which, as has already been suggested, will usually be found in some abnormal condition of the pelvic organs.

The theory which has been held in favor the longest is perhaps that of Bretonneau, who considered that the distention of the body of the uterus by the growing ovum, caused pressure upon, or tension of, the nerve filaments, so setting up a reflex irritation. To a superficial observer this serves as a very satisfactory explanation, yet it fails utterly in many cases and must be rejected as inadequate. This distention occurs in every case, and yet many escape the nausea altogether, while others have it in one pregnancy and not in another. Moreover, the symptoms cease in most cases, while this distention is still going on, and often the cessation is sudden and complete.

Another theory rests upon the supposition of metritis, yet metritis is more common in those who have borne children, while the vomiting of pregnancy is more common in primiparæ.

Still others, notably Veit, believe that endometritis, pre-existing and aggravated by pregnancy, is the source of the reflex irritation. That this may be a factor in some cases is quite likely, but it can hardly explain the phenomena in most, or even in many, cases.

There are those who hold lacerations and erosions of the cervix responsible, but in most cases such lesions do not exist.

Coming now to the theory advanced and ably advocated by Dr. Graily Hewitt, I believe we find the chief, though not the only, cause. He is often quoted as teaching that anteflexion is the sole factor, but this interpretation is far from correct. He finds that "the alterations of the uterus proved by recorded cases to be most frequently present in cases of severe vomiting are:

"*a.* Marked flexion forward and backward.

"*b.* Rigidity of tissues of the cervix.

"*c.* Impaction or detention of the uterus in the pelvis.

"These three factors are most frequently associated in various degrees of severity."

Upon these facts rests his theory that the reflex irritation consists in "undue pressure or tension of the nerve filaments distributed in the walls of the cervix, especially those in the vicinity of the internal os;" . . . "this pressure or tension may arise in any case where that expansion process in the tissues of the cervix which is natural to pregnancy is delayed or obstructed by the condition of the cervix."

Now, if it be borne in mind that during the early weeks of pregnancy the uterus commonly gravitates toward the pelvic floor, it will at once be seen that any previously existing flexion must be exaggerated. If it be still further remembered that the normal condition of the uterus is one of moderate anteflexion, which our modern methods of dress, together with other injurious influences of civilization too often make pathological anteflexion, the preponderance of cases of anteflexion in these statistics of vomiting of pregnancy will not be wondered at.

It will be noted, however, that flexion need not neces-

sarily be present in order to explain the vomiting in accordance with this theory. If by reason of a laceration of the cervix, with subinvolution and chronic metritis as a consequence, the tissues at and about the internal os have become so indurated as to prevent their normal and equable expansion, injurious tension of the nerve filaments is produced. If, again, the uterus be held down in the pelvis by firm adhesions, or by the added weight and bulk of a fibroid, impaction and injurious pressure is just as surely produced as in the case of a flexion.

Other ingenious but less plausible theories have been advanced, but aside from admitting the general truth that almost any form of pelvic disease may in isolated and exceptional cases be a prominent factor, these theories need not be considered here.

My own belief is more liberal than is that of many who have written upon the subject, for while I hold most tenaciously to the general fact of a local cause to be found within the limits of the true pelvis, I yet admit most of the special theories above mentioned. Most prominently I should place Dr. Hewitt's explanation in its broadest interpretation, viz., anything that prevents the free and uniform expansion of the cervix, particularly in the immediate neighborhood of the internal os.

Following this are to be grouped indifferently the various factors of metritis, endometritis, lacerations and erosions of the cervix, and the sundry other forms of pelvic disease which may be operable in rare cases.

Having now ascertained that, whatever the degree of pregnancy vomiting, it springs from some abnormal condition and not at all as a natural and inevitable result of pregnancy, we cannot escape the conclusion that there can be no such thing as "physiological" vomiting, and that, therefore, no difference save one of degree exists between the light and the severe cases. All vomiting during pregnancy, as at other times, is abnormal and must be so regarded and so treated.

Treatment. — It having been established that the chief factor in practically every case of vomiting of pregnancy is some abnormal condition of the pelvic organs, it follows naturally that the most effective treatment must be directed toward the removal or cure of such condition. And just here it should be urged that success in treating the vomiting will be in very close ratio to the accuracy of the diagnosis of the pelvic cause and the intelligence of the treatment applied to it. Let no one who has not good cause to consider himself competent to correctly map out the true condition of the pelvic organs rest content with the delusiou that there is no pelvic cause for the vomiting because he can find none. In such a case no one but a well-trained gynæcologist is competent to pass final judgment, and it must be confessed that even he is fallible.

Most frequent in the list of abnormal pelvic conditions is anteflexion of the body or cervix, associated in most cases with more or less prolapse. For this Graily Hewitt recommends gentle elevation of the base of the bladder and the superimposed fundus of the uterus with the finger. Failing thus he advocates the use of the air-ball pessary, which is to be inflated after insertion. This pessary must be perfectly spherical, and must, when distended, measure not over two and one-quarter inches in diameter, the size rarely needing to be over two inches.

Antiseptic precautions are to be observed before and after insertion, the patient to maintain the horizontal position, and the pessary to be removed at the end of six or eight hours. It may be necessary to repeat this treatment daily until the position of the uterus becomes permanently improved. Care must, of course, be exercised to prevent the induction of abortion by too great or too prolonged pressure due to the presence of the pessary.

Personally I have no experience with this method, though it is a means well worth remembering, but have relied upon the knee-chest position, digital elevation, and packing.

In fact, so common is this condition as a factor, and so effective is the first part of the treatment alone, that I am in the habit of prescribing it as a routine treatment in the ordinary cases of pregnancy vomiting as they present themselves in the hospital clinics and in private practice, and I do not hesitate to assert that relief is complete in eighty per cent. of the cases.

The patient is told to assume a position on her knees, her hips high in air, her chest touching the bed, *every band being loose about the waist*, and then, either by opening the vagina with the finger or by introducing a glass-tube, to admit air to the genital tract. This is done regularly night and morning, and at any other time when nausea is felt.

This failing, I place the patient either in the knee-chest or Sims's position, and, after attempts at digital elevation of the fundus, place a soft but firm packing of cotton tampons *wholly anterior* to the cervix. The first half of the packing is prepared with glycerine, for its depleting effect, the remainder being dry, to act as an elastic air-cushion. In order to get this latter result the cotton must be non-absorbent, the grease in the fibre serving to repel moisture and hold the air.

In one of these ways most cases of pregnancy vomiting may be relieved, but there remain those cases in which other causes are operative.

Retroversion and retroflexion are to be corrected by the aid of the knee-chest position, bimanual manipulation, and packing placed as high up as possible *behind* the cervix and extending down to the perineum. Once replaced the uterus is to be retained by some form of pessary.

In cases presenting erosion of the cervix, and in not a few cases showing no such sign, relief has promptly followed the nitrate-of-silver treatment. Indeed so successful has this treatment proved in some hands that it is now the routine method in the Vienna clinics. It is applied as follows: The cervix is exposed by a cylindrical glass speculum, the end of which it just fills, and after a thorough cleansing enough ten per cent. solution of silver nitrate is poured in to cover the exposed surface. After ten minutes this is decanted and the mucous membrane is dried. A second, and even a third, application may be called for after an interval of two or three days.

Should inflammatory processes be present, either in or about the uterus, the ordinary measures of rest, hot douches, and vaginal medication are in order. It is probably in such cases that benefit is had from vaginal suppositories or dressings of belladonna, cocaine, and morphia.

In all the more serious forms of the complication absolute rest in bed, in the horizontal position, is of much importance. Besides its general therapeutic value it permits the uterus more easily to rise above the brim, and aids us in our endeavors to correct displacements and lessen impaction. Coitus, and whatever may tend to cause sexual excitement or otherwise to increase pelvic congestion, must be avoided.

First discovered accidentally, and then practised empirically, Copeman's procedure has an established place in the treatment of severe cases. This consists in the careful dilatation of the cervical canal up to, but not through, the internal os. The index-finger is used by preference, though Wylie has used in a number of cases a steel-branched dilator. Whether this acts by separating constricting bands of tissue, by straightening flexion, by breaking up impaction, or by some less apparent means, is not as yet agreed, but in many cases where abortion has not resulted a cure has been obtained.

Besides the local cause, however, it is usually desirable to treat the conducting apparatus by which the reflex stimulus is conveyed. In other words, it is well to endeavor to lessen susceptibility to reflex irritation by the use of nerve sedatives, such as bromide, valerian, chloral, and even morphia. Chloral in full dose by rectum, night and morning, sometimes gives great relief, as does also morphia, introduced hypodermically or placed dry upon the tongue.

Chapman's ice-bag to the spine has occasionally been found of service.

Then comes the long list of drugs for lessening the real or fancied irritability of the stomach. These must always be of secondary importance, and yet where symptoms are trivial they may answer every purpose at a min-

imum of annoyance to the patient, and where the outlook is grave we cannot afford to lose any help, however trivial, which may tend toward a cure. While, then, such remedies may always be given a place, reliance should not be bestowed upon them to the extent of wasting valuable time, or to the neglect of more rational measures.

In not a few cases gastric catarrh plays a more or less important part and claims attention. The ordinary remedies may be used, particularly the alkaline salines, taken well diluted before rising. Cocaine in small doses frequently repeated ; creasote, or creasote and comp. tr. iodine in equal parts, given in one-drop doses every half-hour ; oxalate of cerium in five-grain doses alone or combined with bismuth ; calomel and ipecac in minute doses ; hydrocyanic acid ; tr. nux vomica ; pepsin ; ingluvin ; champagne ; hot water ; ice—these and other empirical means may be employed for their direct effect upon the stomach.

The diet and the mental surroundings of the patient must be carefully guarded. Our endeavor must be to keep up the strength at the same time that we spare the atomach needless effort by giving the lightest and most digestible foods. These are best given in small and frequent portions, bearing in mind that often food will be retained if given just after a paroxysm of vomiting has spent itself. It must be remembered also that a patient can sometimes retain and assimilate an article of food for which she experiences a marked longing, when seemingly more appropriate articles are at once rejected. The simple expedient of giving a light and easily digestible breakfast an hour before rising will sometimes solve the problem in those ordinary cases which are known as "morning sickness."

When, however, the stomach rebels to such an extent that the patient's strength perceptibly fails, resource must at once be had to rectal alimentation. Milk, eggs, and predigested beef form the best basis for these enemata, to which may be added, if necessary, a few drops of laudanum and half an ounce of whiskey. Four injections, of four ounces each, given within twenty-four hours, can generally be retained, provided that once daily the lower bowel be well emptied by a cleansing enema of warm suds. Life can be sustained for weeks in this way when all else fails.

Recognizing the fact that mental conditions play an important part in some cases, the patient must be cheered and encouraged at all times, and at the present day it is a pertinent question whether hypnotic suggestion might not prove a valuable aid in properly selected cases.

We now come to that class of cases which resists all the measures at our command. The patient has reached the second stage described above, and the question of emptying the uterus presents itself. Of course it is assumed that no one will lightly decide upon this last resort without good and sufficient cause ; yet on the other hand there is need to urge the danger of too long delay. Provided a faithful trial has been made of less radical measures, and in spite of them the gravity of the symptoms continues, let no time be lost in producing abortion, preferably by emptying the uterus at one sitting, under ether. The reason for thus urging against delay lies in the fact that even abortion may fail to avert the fatal issue if the third stage be permitted first to make its appearance. *Rufus A. Kingman.*

WALLER'S LAW. In 1852, Waller, in his paper in Müller's *Archiv*, entitled "Sur la reproduction des Nerfs," announced the discovery that after section of a peripheral nerve that portion lying beyond the injury suffers characteristic changes. The axis cylinder and medullary sheath degenerate, and the nuclei of the sheath of Schwann at first proliferate and then disappear, leaving only a fibrous rudiment of the sheath in the place of the nerve. Waller explained this degeneration by assuming that the central organ exerts a trophic (nutritive) influence upon the peripheral portion, which influence is removed by section of the nerve. In conformity with this it was concluded that degeneration pursues the path of the stimulus. These conclusions were expressed as the now famous "Waller's Law." In 1868–69 Vulpian published results of a study of the spinal cord of persons who had suffered amputation years previously. He found that the corresponding half of the cord was greatly reduced in size, especially in the segments whose nerves had been amputated. Vulpian discovered only an attenuation of the fibres without any inherent change of structure, but both white and gray substance were reduced in the cord (in some cases in the dorsal, in others in the ventral, cornu). The ganglion cells were normal, and he described the change as simple atrophy. Dickson ("Transactions Pathological Society of London"), in 1873, called attention to diminution in size of the anterior cornu and the degeneration and pigmentation of the cells, and, a little later, Hayem stated that the number of cells is reduced and that the vestiges of the lost cells can be detected. Friedländer and Krause, on the other hand, deny that there is any structural change, and limit the disappearance of ganglion cells to the lateral groups of the ventral cornu. Special importance is attached to the diminution of the dorsal cornu and columns. A disappearance of cells in Clark's columns was also reported. The nerve stump was found reduced in size and about half its fibres diminished by at least a third, with corresponding structural changes. The ventral root is unaltered, while the altered fibres are traced into the dorsal. It is, therefore, concluded that the observed changes are all limited to the sensory fibres and their connections.

Mayser, after eradication of the ischiadicus, detected reduction in the gray matter of the dorsal cornu and some modification of the ventral cornu. Vejas, in 1883, stated that after tearing off the roots of a spinal nerve, the stumps *both* degenerate, and that the ganglion will degenerate after section of the peripheral nerve. Joseph and Kahler, however, very soon after reinvestigated the matter, with results which corresponded fully with Waller's law. Von Gudden and his students have applied the same method to the cranial nerves. When the facial was torn out from the canalis Fallopiæ the root fibres and deeper nidulus disappeared. The root clusters of the eye-muscle nerves were located by the same means. The nidulus of the twelfth was found to atrophy on section of the hypoglossus, though Roller's nidulus was unaltered. Professor Forel applied the same method to the trigeminus and detected great degeneration in the ascending root of the vagus and little in the motor root.

These experiments chiefly relate to young animals, and many of the effects must be ascribed to failure to properly develop on the part of the structures related to the destroyed root. Forel, however, eradicated the facial from an adult guinea-pig, and after one hundred and forty-one days found a total decomposition of the fibres and cells. It must be noted that simple section of the motor nerve root never seems to produce as profound a change as forcibly pulling it out. Forel thinks much depends on the point where the nerve is interrupted. Whether the central portion degenerates or not is largely determined by the relative size of the severed part to the remaining part.

Nissl claims to have observed histological changes in the cells of the facial nidulus twenty-four hours after the eradication of the nerve. These changes consist in partial decomposition of the chromatin figure. On the second or third day the entire cell is affected. On the tenth day many cells have quite disappeared.

In 1890 Singer and Münzer applied the Marchi method to this subject. This method consists in preservation of the tissue in Müller's fluid for three or four days, then dividing into small fragments and leaving six days more, then substituting for Müller's fluid a mixture of two parts of Müller's fluid and one part of one per cent. osmic acid, which is employed for over a week. After washing, hardening is completed in alcohol gradatim, and sections are made in photoxylin. Those portions which have degenerated become intensely blackened, while the normal fibres retain the brown color of the chromic preparation. As a result of this method, Singer and

Münzer decide that Waller's law is correct—that the "ascending degeneration" reported in motor nerves is not a true ascending degeneration such as occurs in sensory nerves.

Bregman, more recently, has applied the same method to the cranial nerves and finds that the motor roots degenerate, but that the degeneration proceeds from the cell outward. Thus Forel's theory is shown to be incorrect, and a genuine trophic influence of the nerve cell is suggested. The degeneration takes place in the same way whether the nerve is sectioned near or far from the point of exit. These pathological phenomena are intimately associated with the physiological results of Gotsch and Horsely. The applicability of Waller's law is not discredited by the fact that even motor fibres may be destroyed by peripheral section, for the source and direction of the changes obey the law that growth and degeneration are governed by the influence of the parent cell. *C. L. Herrick.*

WATER, BIOLOGICAL ANALYSIS OF. Introduction.—Until very recently the examination of drinking-water for sanitary purposes was left entirely in the hands of chemists; but, with increasing accuracy in biological methods and a better knowledge of the living organisms found in water, biological analysis has come within a few years to be considered indispensable in the scientific study of a water. At present neither chemical nor biological analysis alone suffices, but both are necessary, and there is thus no question of the new method superseding the old.

The earliest contribution of importance to biological water analysis was that of Hassall, whose vivid description of organisms and organized detritus found in Thames water in 1850, was largely the means of inaugurating a much-needed improvement in the London water-supply. From this time the examination of water sediments under the microscope began to receive attention. The accurate study of bacteria found in the water was not at that time possible, though it was attempted by Burdon-Sanderson, in 1874, while Pasteur even cultivated pathogenic bacteria from water. Quantitative accuracy first appears in the work of Koch, who examined samples of water by means of his gelatine-plate method, and made a numerical estimation of the water bacteria a comparatively easy matter to all workers.

For several years the advances made in biological water analysis were practically confined to bacteriology, and it was only in 1890 that the ingenious methods perfected by Sedgwick and Rafter enabled the other organized constituents to be studied quantitatively with the same convenience and accuracy as the bacteria.

Qualitative work has lagged behind quantitative, and it is in regard to the nature and significance of the organisms living in water that our knowledge is most deficient. The determination of the species of bacteria, and the relation which they and the other organisms in water bear to public health, are the problems which now engage the attention of workers in this field. The difficulty of cultivating and experimenting with the non-bacterial organisms remains a serious drawback.

With the exception of deep springs or artesian wells, natural waters invariably contain a certain number of organisms; in other words, all surface waters contain organisms. Roughly speaking, the number of organisms present is in inverse proportion to the purity of the water, and hence the importance of quantitative methods. Of aquatic *fauna* and *flora* the bacteria are those most important in relation to public health, owing to the fact that so many of the infectious diseases are known to be caused by bacteria, and that the epidemic outbreak of such diseases is often associated with contamination of water-supplies.

For convenience the subject will be considered under the following headings:

I. Microscopic examination of organisms other than bacteria.
II. Quantitative bacteriological analysis.
III. Qualitative bacteriological analysis.
IV. Pathogenic organisms in water.
V. Bibliography.

(It was originally intended to give diagnostic tables of the bacteria and other organisms found in drinking water, but this has been found impracticable.)

Microscopic Examination:—Organisms other than Bacteria.—Until the convenient and accurate method devised by Sedgwick and Rafter became known, much less progress was made in the examination of the other microscopic organisms as compared with the bacteria. Their examination was conducted, as a rule, in a perfunctory manner, and the possibility of comparison between the results of different observers was very limited. The usual method adopted consisted in allowing the organisms to precipitate in the form of a sediment, of which portions were taken for examination. This sediment was obtained by allowing the water to stand in conical glasses, and be collected from the bottom of these by a pipette at the end of twelve to forty-eight hours.

While this gave a general idea of the nature of the sediment, it gave almost no information as to the amount in which the different organisms were present. Further, those forms which were motile, or lighter than water, were likely to be overlooked. By the Sedgwick-Rafter method all the organisms in a water are strained off by means of a sand filter placed at the bottom of a funnel, through which a given quantity of the water is poured.

The filter is formed by stretching a piece of fine silk bolting-cloth over a perforated rubber cork and forcing it into the outlet of the funnel. Upon this a layer of fine sand, about half an inch in depth, is poured. This sand, having been previously washed with distilled water until the washings are proved microscopically to be free from organisms, is then dried and kept for use. The water to be tested is poured into the funnel and allowed to filter through the sand. As the first 200 c.c. usually comes through rapidly and contains a considerable number of organisms, this amount should therefore be poured back into the funnel. When the amount of water to be examined has run through (500 c.c., as a rule, is a convenient amount) the cork should be carefully withdrawn and the plug of sand (which remains fast in the neck of the funnel) is to be carefully washed out with exactly 10 c.c. of distilled water into a wide test-tube, and shaken up until the organisms entangled in the sand are evenly distributed through the water. 1 c.c. of the washing is then to be withdrawn by a pipette and placed in a special form of cell, which should have a depth of 1 mm. and be 50 mm. in length by 20 mm. in width. The sides of the cells can be readily cut out of soft type-metal at any type-foundry and cemented on glass slides by means of balsam. The capacity of such a cell, when closed in by a large cover-glass, is exactly 1 c.c., and its area is 1,000 square mm.

If one litre be filtered, and 10 c.c. contain the entire sediment, the water is concentrated 100 times, so that the number of organisms found in 10 square mm. of the surface represent directly the number per cubic centimetre. For example—if in the case of the organism Dinobryon, in counting ten squares, we obtain the following results: 0, 1, 4, 0, 0, 2, 0, 1, 0, 0, total 8, we know that this organism is present in an average of 8 per c.c. $\left(\frac{8}{10} \times 1{,}000 \times \frac{1}{100} = 8\right)$. In other words, we divide the total number of organisms found in a given number of squares by the number of those squares, multiply the result by 1,000, representing the proportion which one square bears to the cubic capacity of the cell, and divide by the number representing the concentration of the water.

An error, of course, is multiplied 1.000 times where only one square is examined, and 100 times where 10 squares are examined. To get an absolutely correct estimation of the number of organisms of a given sample, it would be necessary to count the entire 1,000 squares; but I have found that the examination of 10 squares gives sufficiently accurate results. To eliminate a certain personal element, caused by the tendency to overlook

squares containing no organisms and select those containing them, where the distribution of the sediment in the cell is unequal, Rafter has recommended the employment of a rack-and-pinion mechanism, by which the cell is moved exactly one c.c. each time, which forms a valuable addition to the method. The same result can be obtained with any mechanical stage, where movement in each direction is recorded upon a sliding scale.

In the original apparatus introduced, the floor of the cell was ruled into square millimetres, but as this adds considerably to the expense, the ruling is now dispensed with, and, instead, a small disk of metal or black paper is introduced into the eye-piece, having a square aperture cut to correspond exactly with one square mm. on the slide at a given tube length with the objective and eye-piece used. Objective BB Zeiss with eye-piece No. 3 or No. 4, will be found convenient for counting. A high-power lens with a long focal distance is needed for identifying the smaller forms.

To check the results, instead of examining a larger number of squares in the same specimen, I prefer to examine the sediment from two different samples of the same water. If corresponding results are found in each case, the results are evidently to be depended upon, and with careful working I found this usually the case. A certain proportion of the organisms tend to adhere to the sides of the funnel, and these should be washed down with distilled water. It is not advisable to hasten unduly the filtration, one hour being a minimum time for the separation of organisms from a litre of water.

The amount of organized débris and detritus present may also be estimated, and it has been suggested to employ a mental unit by which 20 square microns represent the average area of a single mass of amorphous matter.

Rafter recommends counting the organisms in 20 squares. When 500 c.c. of the water are filtered and washed with 10 c.c., the total of twenty squares gives directly the number per c.c.

The organisms are best registered by genera, under the following headings: (1) Diatomaceæ, (2) Desmidieæ, (3) Chlorophyceæ, (4) Cyanophyceæ, (5) Other Algæ and Fungi, (6) Rhizopoda, (7) Infusoria, (8) Larger animal forms, (9) Miscellaneous and amorphous matter.

A source of error in the system of recording per c.c. is that it is impossible to express numerically the amount in which a given organism is present below 0.5 per c.c., as this number would be given if only a single individual was met with. This difficulty is got over by indicating the occurrence of a solitary organism by the letter *p* (present), to indicate its presence in numbers less than can be expressed quantitatively by the method.

The diagnosis of the organisms in water will probably be found difficult even by those accustomed to microscopic work. To recognize with facility a large number of animal and vegetable forms, presenting few points of distinction, requires special training. Probably those who have amused themselves with dilettante work, making a hobby of the organisms found in ponds and ditches, find less difficulty with the diagnosis than those who have a more accurate, but at the same time more limited, knowledge of biology. The assistance of a skilled botanist or zoölogist is most valuable to a beginner. One of the great difficulties is that no one text-book deals systematically with the diagnosis of the forms likely to be met with in water, and it is necessary to consult a varied and greatly scattered literature.

For sanitary purposes the diagnosis need not be carried beyond the establishment of the *genera*, as we do not know of any cases where particular *species* of algæ, etc., possess any special significance. Though the number of genera to be recognized is large, it bears but a small proportion to the totality of forms described. As a rule, not above 20 different organisms occur in one sample of water, and 200 or 300 genera include the great majority of those likely to be met with. Of course, the more accurate study and determination of species is highly to be recommended, though the results obtained are of scientific rather than of sanitary interest.

Various liquids have been recommended for the preservation and study of the water algæ and infusoria, the most useful agent being a watery solution of osmic acid, of which 1 to 10 drops of a 1 per cent. solution are to be added to 1 c.c. of the water containing the organisms. A gradual addition of the osmic acid prevents the more delicate organisms becoming brittle by exposure to concentrated solution, and at the same time replaces the acid, which is reduced at first by the contact with organic matter. Many forms can be preserved in a 10 to 30 per cent. glycerine solution, which may be lightly tinged with basic aniline or eosin stain. Camphor water, naphtha water, 1 per cent. carbolic or salicylic acid in 25 per cent. glycerine, form preservative media in which the color of the green algæ is preserved; but as a general rule, the trouble of preserving algæ and infusoria in this manner is greater than is justified by the results.

Beyerinck has succeeded in obtaining gelatine cultures of Scenedesmus, Chinella, and a few other algæ in 8 per cent. nutrient gelatine made with decoction of the green scum from stagnant water, and Ogata has isolated certain protozoa and infusoria in this medium.

A fairly large number of observations which we now possess as to the distribution of organisms other than bacteria in certain waters have, it must freely be confessed, not as yet led to any very valuable hygienic deductions, but possibly better results may be looked for in the future. Attempts have been made to trace the association of large numbers of particular organisms with the occurrence of disagreeable odors and tastes in the water, but very little that is definite has been arrived at. G. H. Parker, from an example of 500 samples of water in Massachusetts, of which about half possessed distinctive odors or tastes, found that in 90 per cent. of the waters possessing distinctive odors large numbers of organisms were present, while 90 per cent. of the waters free from strong odors and tastes were characterized by a striking freedom from organisms. As the attempt to associate particular organisms with special forms of odor has led to very discordant results, no specific effects can be set down as the inevitable result of the presence of any one organism.

Sponge spicules have been held responsible for the occurrence of a nauseous fishy taste in waters, largely owing to the fact that they were charged with being the cause of it in one case where a reservoir water was examined by Professor Remson. The presence of large numbers of Cyclops or Daphnia, and the occurrence of Crenothrix, were also thought to account for objectionable flavors and odors in particular waters.

The occurrence of odors and tastes in water does not appear to depend so much upon the *presence* of organisms as to their *destruction in large numbers*, and the putrefactive products from the decomposition of the dead organisms, so that the tastes complained of are probably not due immediately to the organisms found, but rather to the bacteria which decompose them when dead. The presence of accumulations of organisms in reservoirs, supply-pipes, etc., should be studied by comparing samples from different points—the inlet, the reservoir, the outlet, etc.—as they can thus be often located in particular districts.

Sponge spicules appear in abundance only when the spongilla which produce them are being destroyed, that is to say, during the winter months. In the spring and early summer, and during the warm weather, when the sponge growth is most abundant, few spicules are met with. The sponges usually attach themselves to the upper portion of pipes; if attached to the lower side they are apt to be destroyed by accumulation of detritus within their pores (G. H. Parker).

Crenothrix is one of the very few organisms which thrive in the dark; for most other algæ a certain amount of light is necessary to growth. In order, therefore, to secure a water against growth of algæ, filtering basins, reservoirs, etc., should be protected from the light, even a very small aperture being sufficient to admit enough light to allow of considerable growth. On the other hand, access of light is beneficial, as it tends to destroy the bacteria and promote self-purification of the water.

Whether settling basins and filter galleries should be open or covered, is still a question upon which opinion is divided.

The presence of many crustacea, rotifera, and anguillula is regarded as an objectionable feature in a water, though they are present in a number of undoubtedly pure waters, and cannot in themselves be regarded as dangerous.

Pettenkofer and Löwe maintain that algæ, especially Euglena, play an important part in purifying the water, by assimilating the products of decomposition, such as glycocol, leucin, kreatin, and neurin, in weak solutions of which the algæ were found to grow readily.

Extraneous Substances.—Certain organized elements, when recognized microscopically, are indicative of contamination; the presence of meat fibres, squamous epithelial cells, and fragments of vegetable tissue, are to be regarded with great suspicion, as indicating contamination directly by sewage, or by household and kitchen waste. Matters which can be directly traced to the pollution by sewage, form the most objectionable constituent that a water can possibly contain.

Starch.—The occurrence of starch granules in water is a feature which has, apparently, received a wrong interpretation. It is usually stated that starch indicates contamination by food-products, and that partially digested starch, whose granules can be identified with corn, potato, etc., is a direct proof of contamination. The writer was considerably surprised to find that the water of the Ottawa River (a stream so large as to render contamination of its total volume out of the question) habitually contained starch granules. These were present at all seasons of the year in numbers varying from 0.3 per c.c. to 3 per c.c., and water of the Montreal supply derived from this source, collected from districts where the circulation in the mains was defective, even contained as many as seven granules per c.c. As this was the only suspicious feature of the water, it was difficult to reconcile such large quantities of starch with the fact that chemical and bacteriological examination pointed to a remarkable freedom from contamination.

Further study of the characters of the starch granules showed that they corresponded exactly in form, size, markings, and polarization to corn-starch. The introduction of corn-starch from the waste of factories could not be seriously imagined, as no such establishments are to be found along the course of the river, and on the other hand, the St. Lawrence water was never found to contain starch, although several large starch factories exist on its banks. In any case, the aim of a starch factory is to save its refuse, and not to throw it away, and, as a matter of fact, the profitable working of a starch factory depends largely upon the careful saving and selling of the waste. What appears to be the correct explanation of the presence of starch in Ottawa waters was suggested by Dr. G. P. Girdwood, of Montreal, namely, that it was derived from the bark of the white pine, of which 3,000,000 to 10,000,000 logs are sawn every year in the Ottawa districts, the sawdust being thrown into the river and accumulating there in quantities sufficient to produce obstruction to navigation.

An examination of the bark of the white pine showed it to contain numerous starch granules, which, as will be seen from Figs. 655, 656, 657 correspond closely both to the starch found in the water, and to corn-starch. The somewhat greater tendency to a rounded outline found in the starch in the water, compared with that in the fine bark, is probably due to the effects of soaking, and the change due to maceration of white pine starch, as shown in Fig. 658, where the outlines simply become rounded, distinguishes it from the maceration effects of corn-starch, where the granule becomes brittle and splits up into segments, as shown in Fig. 659.

The derivation of starch from aquatic plants natural to water was also a source to be borne in mind, but the writer was unable to find any water-plants which contained granules corresponding to those found in the Ot-

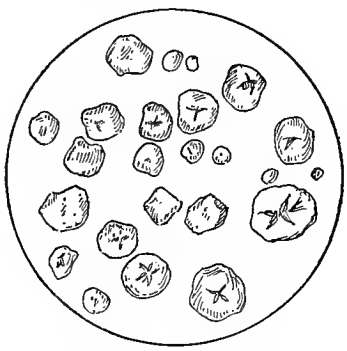

Fig. 655.—Corn-starch. × 200.

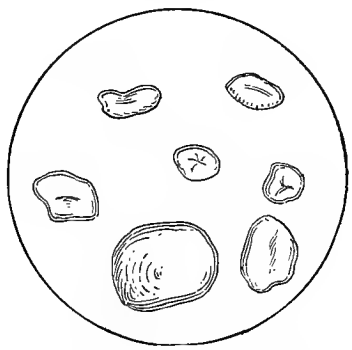

Fig. 657.—Starch Grains from Montreal Water. × 200.

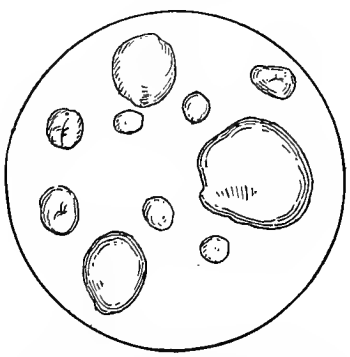

Fig. 658.—Starch from White Pine after Maceration. × 200.

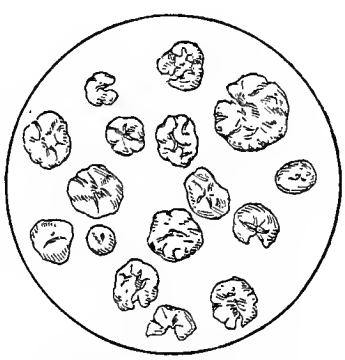

Fig. 659.—Corn-starch after Maceration. × 200.

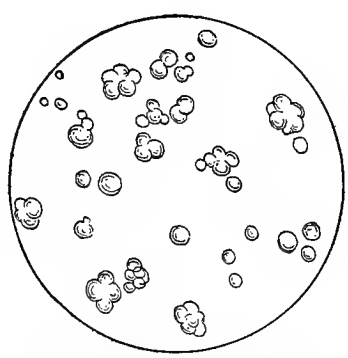

Fig. 660.—Starch from the Yellow Water Lily (Nuphar). × 200.

tawa water. The only two plants likely to produce starch in sufficient quantities to enable its presence in the water to be detected, are the Yellow (Fig. 660) and White Water Lilies *Nuphar Nymphæa*, and the Wild Rice or Water Oats (Fig. 661), in both of which the granules are not only considerably smaller, but of a different shape and outline from those found in the Ottawa.

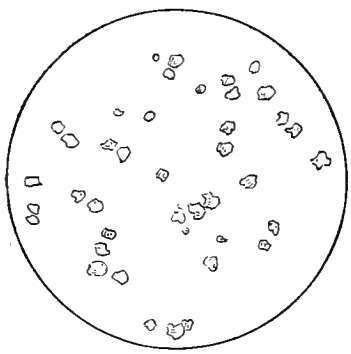

FIG. 661.—Starch from Wild Rice. × 200.

The rhizome of the sweet flag (Fig. 662) also contains numerous starch granules, considerably smaller than those of corn. As an aid in distinguishing starch corpuscles from these different sources the following table of dimensions will be found useful:—

Starch granules from.	*Size.*
Water sediments	11.4 to 28.0 μ
White pine bark	8.0 to 28.0 μ
Corn	5.7 to 27.0 μ
Sweet flag	6.0 to 13.0 μ
Wild rice	5.7 to 13.0 μ
Nymphæa (white water lily)	1.9 to 7.6 μ
Nuphar (yellow water lily)	3.8 to 13.3 μ

(After Professor D. P. Penhallow.)

The presence of starch in a water may thus be accounted for without necessitating the assumption of sewage or industrial pollution. Besides the sources mentioned above, it is probable that others exist, as the writer

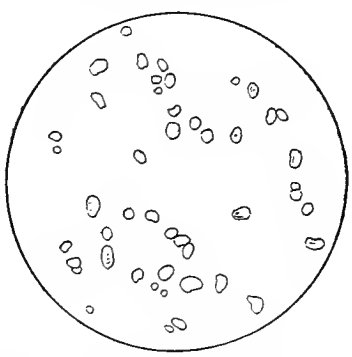

FIG. 662.—Starch from Sweet Flag Root. × 200.

has found starch granules not dissimilar to those mentioned in waters where pollution by sawdust was out of the question. The subject is one requiring further study and observation.

The presence of textile fabrics, etc., is occasionally noted where waters receive the washings of factories, but probably a large number of the observations on this head are due to errors in manipulation, where the cloths used in cleansing the apparatus have been the real source of the fibres. When an examination for fibres is to be made, a large amount of water—several gallons—or in the case of a tap-water, several hundred gallons, are to be strained through a glass wool filter; the filtering substance can then be crushed and examined in a Petri dish. It is rare with these precautions to find any trace of fibres.

Human and animal hairs are said to have been found, both in the water and in ice, but rarely by experienced observers; and the observations probably often rest on erroneous grounds.

A fecal origin of contaminating substances is not established with certainty by the detection of vegetable kitchen refuse. These fragments of starch do not always give the iodine reaction. If fragments of boiled starch-grains are found in a water it points to a contamination by kitchen refuse.

The detection of particles of meat fibre in a water is of more significance, as meat is not digested to the same degree as starch, and small muscle fibrils are always present abundantly in stools. Both raw and cooked muscle-fibres present, under the microscope, distinct striation and sharp ends, and are of a grayish color. When, however, a muscle has been partly digested, it appears as golden-yellow, glistening masses, with rounded outline and blunted angles. The striation may be either preserved or entirely absent. The arrangement in bundles is sometimes clearly seen. The masses burst upon pressure. When seen in a bright microscopic field, the yellow coloration by bile-pigment is often very marked, and may be retained after three or four weeks' standing in frequently changed water (Gaertner). The detection of such particles in a water, as, for instance, was accomplished by Snow, in the case of the Southwark and Vauxhall Company in London, is sufficient evidence to establish with certainty that contamination with fæces has taken place.

Intestinal epithelium, fat crystals, mucus, connective tissue, elastic fibres, etc., have scarcely ever been detected in water.

PARASITIC ORGANISMS IN WATER.—*Malaria.*—That malaria prevails only in damp, ill-drained regions is a fact of such general experience, that there can be no doubt that the plasmodium malariæ is, for its development, dependent in some way upon water. The entrance of the parasite into the human system appears to be accomplished by inhalation of miasmatic vapors rather than by drinking the water. A number of forms allied to the *plasmodium malariæ* are found in the amphibia (Danielewsky), and recently Coronado claims to have succeeded in cultivating the plasmodium of Laveran in water from a malarious stream.

Filaria sanguinis hominis appears to be connected with damp regions, but probably the infection is accomplished by the aid of an intermediary host (mosquito), and not directly from the water.

The *filaria medinensis* is not infrequently found in the cellular tissue of man. The embryos have been traced to small crustacea. (Cyclops.)

The *distoma hepaticum*, in its embryo stage, infests the small form of water snail (Limnæus minutus).

Distoma hæmatobium, found chiefly in Africa, has proved fatal to man. The ova infest small mussels and water insects, as intermediary hosts, and these are supposed to be ingested by drinking-water.

Parasitic Ova.—The ova of many parasitic entozoa retain their vitality for a long time in water, and some forms, notably the *Bothriocephalus latus*, become, in one phase of their development, free swimming embryos. The direct use of this water by man, for drinking purposes, is not dangerous, but fish (pike) in waters containing the dejecta of patients harboring bothriocephali, develop the cysticercus stage of the parasite, and fish from such waters, if imperfectly cooked, are known to give rise to *Bothriocephalus* in man.

Tænia mediocanellata is not directly produced in man by ingestion of fluids containing the ova, and *Tænia solium* is rarely so, but the intermediary hosts, cattle and hogs, are probably often infected by drinking-water containing the ova.

Echinococcus has never been shown to be transmitted through means of water.

Of the platode parasites, *Distomum* is certainly trans-

mitted by water to cattle, as the disease usually appears where the pastures are unduly damp.

Of the nematodes, a large number of those infesting the lower animals, notably *Filaria*, *Strongylus*, *Pseudalius*, etc., appear to be frequently derived from the water.

Of the nematodes infesting man, only one, *Anchylostomum duodenale*, has been clearly traced to this cause, where, as in the case of the laborers in the St. Gothard tunnel and in certain brick-yards at Cologne, water polluted by the dejecta of persons suffering from the parasite was drunk by the other workmen. Attention to this point eradicated the disease.

The parasites, *Ascaris*, *Oxyuris*, and *Trichocephalus*, are probably occasionally transmitted by drinking-water, though the individual cases are difficult to trace.

Trichina does not appear to have been communicated to water.

The tropical dysentery, which we now know to be due to the *Amœba coli*, is thought to be communicated by drinking-water, though more objective proof is wanting on this point.

Bacteria in Water.—*Distribution.*—Bacteria are always present in surface soil in large numbers, and from thence gain access to the water, where, if they find conditions suitable to their development, they increase.

As the atmosphere near the earth's surface always contains bacteria, a certain proportion must naturally be derived from this source, though, as micrococci and molds, which form a large percentage of the organisms found in air, are rarely met with in water, it is evident that the number derived from the air is comparatively insignificant.

A surprising fact, demonstrated first by Koch and elaborated afterward by Fränkel, is that soil and the water which percolates it, only contain bacteria at points very near the surface; so that soil and soil water, at depths greater than two metres, are almost always practically free from bacteria, although the humus at the surface may contain millions of bacteria per c.c. This is, no doubt, due to the fact that, by its mechanical filtering power, the earth retains the bacteria and withdraws them from the water passing through it. *Deep ground-waters under normal conditions contain no bacteria.*

Most of the water bacteria belong to the class of bacilli. The presence of cocci points to transient conditions by which these organisms have recently entered the water from the air or the soil, and have not yet had time to die out.

This preponderance of bacilli in water was first observed by Koch, and has been confirmed by most observers. Although quite a number of species of cocci have at various times been isolated from some waters, the writer's experience of the large Canadian rivers, St. Lawrence and Ottawa, was that normally only bacilli were present, and that cocci and molds represented a transient contamination (usually indirectly from the air, as when following the melting of snow). Micrococci are chiefly met with in small bodies of water, such as brooks, wells, or aqueducts, and probably show that the water is exposed to minor degrees of soil or dust contamination. The presence of micrococci in a natural water is, therefore, an unfavorable sign, though it does not necessarily indicate harmful pollution.

The depth at which bacteria are present in soil and ground-water varies with the nature of the soil and the locality. C. Fränkel found at times 100 to 600 bacteria per c.c. in ground-water where the soil nearer the surface had been free from bacteria. Loose and sandy soils yield bacteria at a greater depth than denser strata. The soil in cities usually presented a somewhat deeper layer of earth containing bacteria than was found in uninhabited spots, though this difference was not very striking, and the soil beneath streets and houses, or even in the vicinity of sewers, was practically sterile at a depth of 3 to 5 metres.

The soil in grave-yards was found by Beumer and also by Gärtner, to show bacteria at greater depths than would be expected in other localities, and in one instance the ground-water at 2.5 metres contained 27,000 bacteria per c.c. Anaërobic bacteria are practically absent from the deeper strata, so that the exclusion of oxygen does not appear to be an important element in determining the absence of bacteria.

The temperature of the soil, though varying from 2.5° C. in March to 14° C. in August at 1.5 metre, and from 8° C. in March to 13° C. in September, did not appear to influence the number of bacteria present (Fränkel).

Recently, Esmarch has investigated the old graveyard soil in the grounds of the Charité Hospital, at Berlin, and arrived at conclusions corroborative of those mentioned above.

The distribution of bacteria in natural waters is a subject upon which our knowledge is very incomplete, owing to the fact that the number varies in the same locality at different seasons of the year, and the examinations have not, as a rule, covered long periods of time. Also, methods for taking samples are so diverse that it is hard to compare the results of one observer with those of another. In particular, the results of examinations of well waters are so modified by the state of the pumps, by which such samples were usually obtained, as to render them almost valueless. It may be stated generally that the water of shallow wells and surface springs contains the same number of bacteria as surface water, usually several hundreds or thousands per c.c. Deep wells and deep springs contain the same number as ground-water (from 0 to 10 per c.c.), unless extraneous sources of pollution exist. The water of flowing streams usually contains from 50 to 1,000 per c.c., and the water of large standing bodies of natural water, such as fresh-water lakes, from 0 to 10 per c.c. Sea water has not been frequently analyzed, but the results show that it is relatively rich in micro-organisms as compared with fresh water (Russell).

Rain and snow near the surface of the earth invariably contain a certain number of micro-organisms. The average number contained in the rain-water at Montsouris observatory, near Paris, for the three years, 1883–86, was 4.3 bacteria, and 4.0 molds per c.c., which, with a rainfall of 60 c.c., signified that about 5,000,000 germs fall annually for each square metre surface in that locality (Miquel). Melted snow is stated by Miquel to contain fewer bacteria than rain-water. Hail was found to contain 729 organisms per c.c. (Foutin) at St. Petersburg, and on another occasion 705 per c.c. at Baltimore (A. C. Abbott). At points distant from the earth's surface, such as the summits of lofty mountains or several hundred miles out at sea, the air has been found quite free from bacteria. It is considered that bacteria are not carried into the air by the mere process of evaporation, but only where dust is present. Snow usually contains a larger number of micro-organisms than are found in ice (Prudden), molds and micrococci being abundantly represented.

The conditions determining the amount of bacteria in natural waters are varied. Surface soil and dust form the great depot of these organisms, and their increase naturally depends on whether conditions favorable to their development are present or not. Warmth, moisture, and a sufficient amount of suitable nutrient substances favor growth; dryness and cold check the growth of most bacteria, but kill only a few of the more delicate species. The nutriment most favorable to particular species is very diverse. The water bacteria proper find in pure distilled water a medium sufficient to produce millions of organisms per cubic centimetre, in the course of a few days. Some forms, again, only flourish when a certain amount of proteid, such as peptone or albumin, is present; while, on the other hand, the group known as nitrifying organisms only grow in saline media from which albuminoids are absent. Some grow best in acid, others in alkaline media. Certain bacteria form products favorable to the growth of their own or other species, while others produce bodies having inhibitory powers which render the water infertile and incapable of supporting bacterial life (Miquel). The phosphorescent group and some forms peculiar to sea-water require the addition

of more sodium chloride to their culture media. Some grow only at low temperatures, 0° to 10° C., while others grow only at temperatures higher than that of the body, 40° to 60° C.

Fortunately, as far as we are aware, none of the pathogenic bacteria are capable of developing in water to any considerable extent, and as, even in impure water, the other forms present tend to destroy the disease-producing germs, unless a water is exposed to repeated infection, dangerous conditions tend to disappear. On the whole, the general tendency of the results of bacterial life in water is to purify it and to remove noxious substances.

The number of bacteria in a water affords an excellent indication of its cleanness, and, for this object, affords an even more delicate and reliable index than chemical analysis. Although it is hardly possible to state arbitrarily what degree of purity may be represented by special numbers of bacteria to the cubic centimetre,* which has been accepted by common consent as the standard unit of comparison, the following scale, suggested by Miquel, is very convenient to bear in mind:

MIQUEL'S SCALE OF PURITY OF WATER.

Exceptionally pure water contains	0 to	10 bacteria per c.c.
Very pure water contains	10 to	100 bacteria per c.c.
Pure water contains	100 to	1,000 bacteria per c.c.
Poor water contains	1,000 to	10,000 bacteria per c.c.
Impure water contains	10,000 to	100,000 bacteria per c.c.
Very impure water contains	100,000 and	upward bacteria per c.c.

By employing the words *clean* and *unclean* the scale is made to represent better our ideas as to the sanitary value of such results, since, as Miquel admits, a water classed as "pure" or "very pure" here would have to be branded as dangerous if any part of the small number of bacteria happened to be pathogenic germs. Still, to express the idea of relative cleanness, this scale answers very well.

According to Koch, water habitually containing above 100 bacteria per c.c. ought not to be employed for drinking purposes, and in filtered water the presence of more than 100 bacteria per c.c. is sufficient evidence that the filters are not working properly.

General meteorological conditions have an important influence in modifying the number of bacteria in water.

The *temperature* of the water or air, contrary to what might be expected, has very little effect upon the number of bacteria present. In waters which range at different seasons between 0° C. and 20° to 22° C., the number of bacteria never rises proportionately to the increase in temperature, and the maximum number usually occurs at a time when the temperature is lowest. The writer found, in the case of the Ottawa and St. Lawrence Rivers: (1) That the maximum numbers of bacteria per cubic centimetre were met with in the early spring and at the onset of the winter; (2) that no gradual rise in the number of bacteria accompanied the steady increase of temperature during the early summer; (3) that the number of bacteria during the three warmest months was lower than at any other period; and (4) that the number during the winter did not fall materially below the average for the entire year. These observations, made upon rivers of enormous size, where local contaminating causes were reduced to a minimum, correspond closely with those published by Miquel, who found that in the rivers near Paris the greatest number of bacteria was met with during the winter. In Miquel's observations it is interesting to note that the maximum numbers were found in February and the middle of December—seasons corresponding closely with April and November in Canada, when the difference in climate is taken into account. It is not generally known that in the winter the temperature of large rivers is 0° C., even at the bottom of the stream; thus cooling the whole body of water to the freezing point, even when the current is almost imperceptible. This was observed in the water of the St. Lawrence by Professor Goodwin, at Kingston, Ontario, and in the Ottawa and St. Lawrence at various points by the writer. (Figures 663 and 664.)

ICE.—With *temperatures below the freezing point* the case is somewhat different. Ice always contains far fewer bacteria than the water from which it is formed. The results of different investigators on this subject vary widely. Fraenkel found that the number of bacteria in natural ice supplied at Berlin ranged from a minimum of hundreds to a maximum of thousands per cubic centimetre, while ice artificially prepared from distilled water was practically free from bacteria. Prudden found that the physical characters of the ice played an important part in determining its bacteriological purity. Clear ice always contained a smaller number than ice with air-bubbles, and the latter again less than the surface ice, which contains snow. This snow ice, he maintains, should never be used for drinking purposes. By experimentally freezing water containing various species of bacteria, Prudden found that some germs possessed greater resistance than others. With typhoid bacilli, for instance, about ninety per cent. were at once destroyed by freezing, but a certain proportion withstood one hundred and three days' freezing. Repeated freezing and thawing were found more efficacious than uninterrupted freezing alone, five alternations of thawing and freezing sufficing to destroy all typhoid bacilli. From this it seemed that the crystallizing process of freezing acts mechanically in injuring the bacteria, although Prudden, strange to say, found that when the temperature of water was reduced below the freezing point, and freezing prevented by coating the surfaces and sides of the vessel with oil, an even more energetic germicidal action was obtained than by repeated freezing and thawing (moist cold acting, apparently, in a manner analogous to moist heat). Bordoni-Ufreduzzi found that while about ninety per cent. of the bacteria in water were instantly destroyed by freezing, no further reduction in number took place, even if the ice were kept frozen for several months.

All observers agree that the freezing of an impure water does not render the ice fit for human consumption, and the general result of the investigations has been to show the superiority of artificial ice supplies over the natural ones, except when the water of the latter is exceptionally pure. Heyroth, however, found that the artificial ice supplied in Berlin often contained large numbers of bacteria, a condition traceable sometimes to the fact that impure water was originally used for its manufacture; at other times to contamination of the ice, during or after the process, by unsanitary conditions of the machinery, store-houses, etc. He urges the necessity of such establishments being placed under sanitary supervision.

A recent investigation into natural ice supplied in Paris from impure ponds and streams, showed in all cases such dangerous impurity as to cause its use for purposes of alimentation to be prohibited.

The Massachusetts State Board of Health, as a result of an extended series of investigations of the rivers and ponds of Massachusetts during the winter, arrived at conclusions similar in the main to those of Prudden. It was found that the ice contained, chemically, less organic matter than the water from which it was derived, and a notably less number of bacteria. Chemical investigations were made as to the effect upon the water of being frozen over, and it was found that this appeared to exert an unfavorable influence upon the natural processes of self-purification; so that winter water is, if anything, somewhat inferior to that obtained from the same source during warm weather. The lower portion of a cake of ice contained fewer bacteria than ice of the same transparency near the surface. In this connection it must be remembered that the numbers of bacteria, as obtainable by the gelatine plate method, only represent one phase of aquatic bacterial life. The nitrifying organisms, which are the agents by which the final and most important steps in the oxidation process is accomplished, appear, from chemical analysis, to be incapable of working at temperatures below 13° C. Though the biological side of the question

* A cubic centimetre contains approximately 15 minims, or a quarter of a teaspoonful.

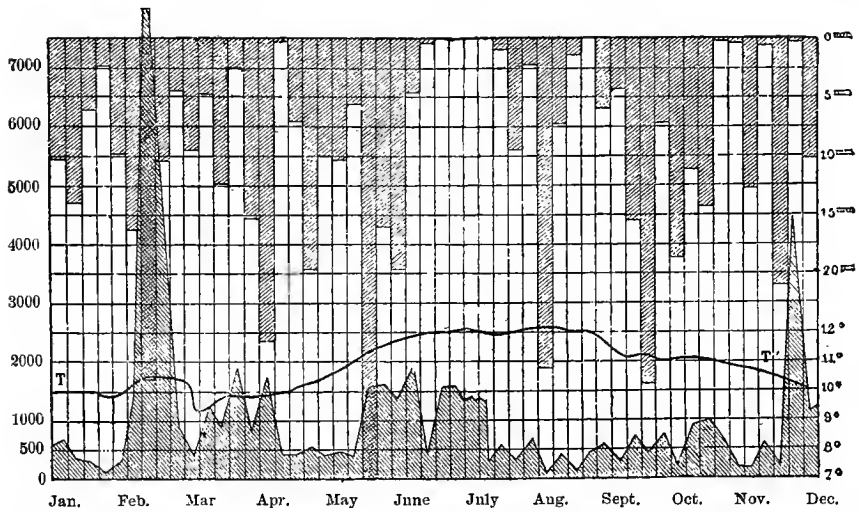

FIG. 663.—Diagram Showing the Relation between Rainfall and Bacteria in Water during 1889. Montrouge reservoir, Paris (Miquel.) By mistake a rainfall of 12 mm. in the second, third, and fourth weeks of July has been omitted. The truncated columns give the rainfall, the pointed ones the number of bacteria per c.c. TT', temperature.

an area of over half a million square miles, much of which is uninhabited country where no meteorological stations exist. Hence the local rainfall, as observed at Montreal, did not correspond as closely to the fluctuation in number of bacteria as did the water-level. The increase evidently depends upon the washings of alluvial soil, and not on the direct access of rain, as in the greatest increase, that of the spring, the rise of river-level is mainly due to a general melting of snow and relatively little to rainfalls.

In Miquel's diagram of a water obtained from a comparatively small water-shed, the local rainfall coincides accurately with rises in the number of bacteria.

has not yet been worked out, it is clear that a lowering of the temperature in water is not by any means an unmixed blessing, as a water is not only not directly improved by cooling, but is even prevented from purifying itself.

ICED WATER.—The evidence adduced shows the advisability of cooling water by other means than the direct introduction of ice, which may contain sufficient bacteria to pollute the water. Contamination of drinking-water by ice is to be prevented either by obtaining a pure natural supply in the first instance, or by manufacturing it from pure natural or distilled water under suitable conditions. When this cannot be done, care must be taken that the ice used in coolers is not put directly into the water, but into a separate cooling chamber. In hot, dry climates an admirably cool and refreshing water is obtained by allowing it to stand in vessels of porous earthen-ware,* enough evaporation taking place through the sides of the vessel to keep the water at from 10° to 12° C., even in the hottest weather, without the employment of any ice at all. The practice of drinking ice-water habitually can hardly in any case be considered to rank among our national virtues, though it is stated on good authority that where serious gastro-intestinal disturbances have been traced to the drinking of iced water, either the water or the ice was found, upon analysis, to be impure.

Barometic pressure appears to exert no influence upon the number of bacteria found in water.

Rainfall and melting of snow appear to be the chief factors affecting the number of bacteria in natural waters. In the writer's experience of Canadian waters, seasons of heavy rainfall were attended by marked increase in the number of bacteria. This accounts for the increase in bacteria noticed just before the onset of winter, a time at which all the rivers become full. The water-level of the river was found to be a better index than the observed rainfall, as the watersheds of the Ottowa and St. Lawrence cover

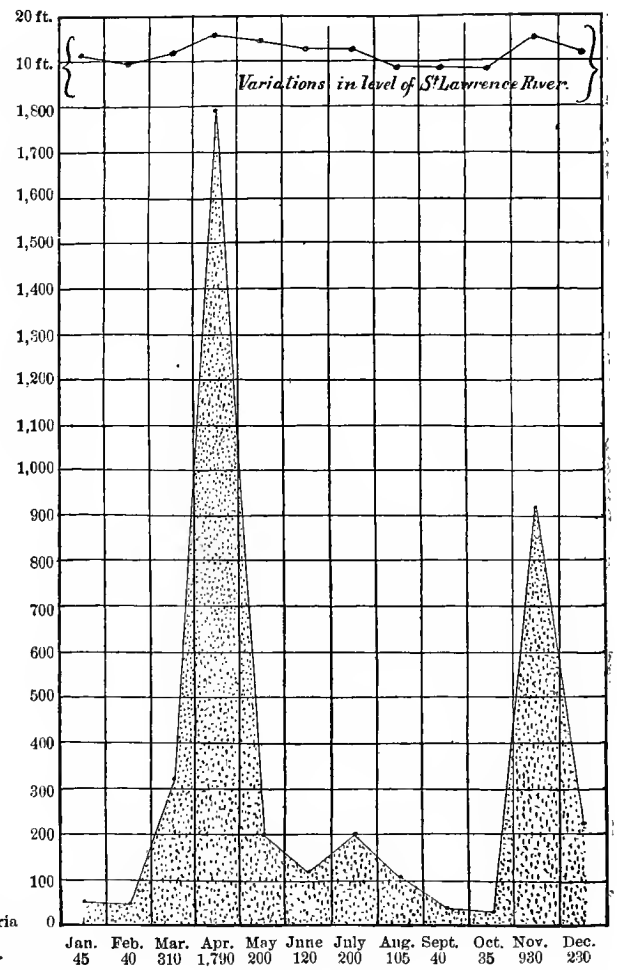

FIG. 664.—Diagram Showing Average Number of Bacteria per c.c. in Montreal Water, during 1891. (Johnston.)

* Darlington has stated that water cooled in this manner soon becomes offensive, probably owing to infection by bacteria remaining in the pores of the earthenware. This was especially noticeable in water which was boiled previously to being placed in the jar. He recommends the use of glazed jars covered with moist cloths.

Influence of Seasons.—From the preceding it will be seen that the variation in the number of bacteria in a water is chiefly determined by the degree of its exposure to contamination by substances containing large numbers of micro-organisms, but above all, by the washings of soil. Seasonal variations in the number of bacteria vary with the different climates. In analyzing the statistics bearing upon this point certain precautions require to be taken, which have obliged the writer to discard a large number of otherwise valuable observations as being open to too great sources of fallacy. In particular, the elaborate weekly analyses of the Spree at Berlin are nearly valueless for general statistics upon meteorological influences, however important they may be from a local hygienic point of view, or in showing the efficiency of the filtration methods employed. In Plagge and Proskauer's observations, as well as those of G. Frank, the difference between the numbers obtained in various months was far less than that obtained in individual observations during the same month. For instance, with weekly analyses, the average numbers of bacteria (per c. c.) found in unfiltered Spree water, in each month in 1884–5, was as follows:

1884.

July.	Aug.	Sept.	Oct.	Nov.	Dec.
1,064	1,440	2,496	3,251	3,466	811

1885.

Jan.	Feb.	March.	April.	May.	June.
864	685	1,843	1,698	381	6,190

showing an apparent falling off in number during the winter, with a minimum in May. In the following year the result obtained was:

1885.

	June.	July.	Aug.	Sept.	Oct.	Nov.	Dec.	Jan.	Feb.	March.
Min...	4,400	2,640	1,800	960	1,204	5,520	2,700	1,100	1,250	1,010
Max...	7,980	110,740	11,900	9,200	4,840	31,500	9,000	29,000	20,000	100,000
Av....	6,190	56,690	6,850	5,080	3,020	17,010	5,850	15,050	15,625	50,505

It is evident here that the variation between the result of different collections in the same month may not only be ten times as great as the maximum range of the monthly averages, but in each month the minimum single observation falls lower than the minimum average for the ten months. It is clear that small streams like the Spree are quite unfitted for the work of furnishing data for general application. The work is further vitiated in a number of valuable memoirs by the fact that no statement is made as to the variations in the numbers of bacteria found in individual samples collected at the same time. Work of this kind should always be done in duplicate, and the full details given for purposes of control.

Bacteria per c.c. in Seine water, taken at:

Season.	1888. Months.		Pont d'Ivry.	Pont d'Austerlitz.	Marne at St. Maur.
Winter.	December. January. February.	.....	14,350	41,536	70,990
Spring.	March. April. May.	.....	47,234	66,084	20,204
Summer.	June, July. August.	.....	6,080	13,666	6,683
Autumn.	September. October. November.	.....	55,700	45,940	38,029

Information of far more value has been obtained from the examination of larger streams, and the results of Miquel from the Seine and Marne waters are probably a truer index of the influence of seasons on bacteria in water. From certain peculiarities in his methods the number of bacteria given by Miquel is greater than would be indicated by the gelatine-plate process.

Here it is seen that the minima occur in the summer and the maxima during the winter.

Analogous results were obtained by Smith in the water of the Potomac, and it may be inferred that this condition fairly represents the behavior of large streams, under natural conditions. Griffith found in the water of the river Witham, at Lincoln, the following means: Winter, 5,097; spring, 11,300; summer, 11,092; autumn, 7,980. It must be remembered that the summer is in England a season when much rain falls.

Although, as a matter of observation, the number of bacteria in natural waters does not seem to diminish notably during winter, there can be no doubt that the continued low temperature of the water not only checks the natural increase of bacteria in water, but actually tends to destroy their vitality. In water allowed to stand at temperatures of 18° to 22° C., a great increase in the number of bacteria takes place within the course of a few days, so that water containing less than 100 per c.c. will usually be found to yield about half a million per c.c. after three or four days. At lower temperatures the increase is less marked, but even at 6° C. a marked increase in certain species has been noted after a few days (Bolton).

On the other hand, in water kept at 0° C. the same observers observed a marked diminution, especially among the liquefying forms, as is seen from the following figures (the numbers in parentheses indicate liquefying forms):

Days at 0°.	Bacteria per c.c. (before.)	Bacteria per c.c. (after.)
1....	148 (14)	126 (6)
1....	150 (11)	115 (2)
2....	123 (14)	69 (0)
2....	158 (15)	101 (0)
3....	129 (9)	29 (0)
3....	156 (11)	33 (2)

It appears, therefore, that the influence of cold, when sufficient to lower the temperature of the water to 0° C., must tend to greatly diminish the number of bacteria present, so that any marked increase observed in winter is to be ascribed to conditions tending to introduce bacteria into the water from without. That in natural waters no marked diminution in number occurs in the colder months, may also mean that *some more powerful restraining influence than low temperature is held in check during the cold period.* The results by the Massachusetts State Board of Health show that the nitrifying processes in water cease when the temperature falls below 14° C., and are only resumed when it again rises. In the same reports it is repeatedly shown that when nitrification was in full progress the numbers of bacteria in sewage, etc., were being markedly diminished, though the idea that nitrification is an agency by which bacteria can be destroyed is not formulated. Consideration of the fact that a marked fall in the number of bacteria always occurs during the warm months, when nitrification can be shown to be most active, seems to justify the view that the nitrifying process in some way tends to restrain bacterial growth in natural waters, sewage, etc., and that the removal of this restraining or destructive influence in cold weather compensates to some extent for the reduction effected by cold, so that the bacterial death-rate, so to speak, remains stationary.

Though the number of bacteria is nearly as great in natural water in winter as in summer, the species are different. This was brought out by a comparison of the principal forms met with in Ottawa water, during the summer and winter, respectively. During the summer, one species, the bacillus fluorescens liquefaciens,

formed about thirty to forty per cent. of all the colonies; but during the winter this organism was only present in the proportion of two per cent.; and the bacillus aquatilis, and some allied organisms, scanty in summer, formed fully twenty per cent. of all colonies in winter.

Light.—It has long been known that bacteria grow best in the dark, and recent experiments have shown that direct sunlight has strong germicidal powers over many bacteria. The experiments of Buchner and others show that both liquid and solid cultures of typhoid bacilli and bacillus coli communis were killed by exposure to direct sunlight for half an hour. Buchner suggests that this action may have an important bearing upon the diminution of bacteria in standing bodies of water, and suggests that settling basins should be shallow and lined with some white material, in order to obtain the full benefit of the bactericide action of light. Proof as to the depth to which the sun's rays can exert any bactericidal action in various waters is not yet forthcoming, and in the case of brown peaty waters it is unlikely that this action is sufficiently pronounced to account for the small number of bacteria usually found in these waters. On the other hand, some grounds exist to show that a reservoir or settling basin may possibly be better left open than covered in, contrary to the generally accepted opinion.

Motion and Rest. *Motion.*—Although there is some discrepancy between the results of individual observers, it appears clearly established (Cramer, Miquel, Gärtner) that agitation of a water exerts no influence upon the number of bacteria in it. For instance, Miquel found that on taking a sample of water from the Vanne, which contained originally 28 bacteria per c.c., and dividing it into two portions, one of which was constantly shaken at the rate of two hundred and fifty shakes per minute, while the other was left at rest, at the end of twenty-four hours the flask which was shaken showed 71,000 bacteria per c.c., and the one at rest 80,000 per c.c. Another sample taken from the Marne, which showed at first 65 bacteria per c.c., increased to 43,000 per c.c when shaken, and 31,000 when at rest. No significance attaches to these slight variations. The motion which water undergoes in passing through supply mains does not seem either to increase or lessen the number of bacteria present (Wolffhügel, Proskauer).

Rest.—A state of rest in natural waters exercises a very marked influence in diminishing the number of bacteria. In fresh-water lakes formed by the expansion of large rivers, the lake water always contains far fewer bacteria than that of the streams entering it. In the Ottawa River, which has an average width of about half a mile, an expansion occurring above Ottawa is called Lake Deschênes, and another, about one hundred miles lower down, is known as the Lake of Two Mountains. The width of these lakes is over two miles, and their average depth thirty to fifty feet in most places. A quite perceptible current passes through them, though its velocity is less than one-sixth that of the river proper. Above the Lake of Two Mountains the river water never contained less than 30 to 60 bacteria per c.c., while in the lake it only averaged 5 per c.c., the maximum being 14 per c.c., and a majority of the samples yielding no colonies whatever by the gelatine-plate method. The water of Lake Deschênes contained from 0 to 20 bacteria per c.c.; whereas the river about five miles lower down contained 120 to 200. In Lake St. John, which forms the head-waters of the Saguenay, the average of four large rivers entering was 240 per c.c., and the lake water contained from 0 to 16 bacteria per c.c. The River Saguenay, which forms the outlet, was found to contain 50 to 60 per c.c. The Spree, which enters the Lake Havel a few miles below Berlin, with water containing 190,000 bacteria per c.c., on leaving it contains only 9,200 per c.c. (Frank).

It is thus clear that the state of rest in a natural water does not lead to any of the objectionable features which we are accustomed to associate with the idea of stagnation, but is, on the contrary, one of the most powerful agencies by which the self-purification of water is secured. The statement, formerly current in text-works on hygiene, that motion, as found in running water, was a valuable aid in purification does not seem to rest on any definite observations. It is possible that, as water in running rapidly over the bed of a stream must be brought into intimate contact with the material forming that bed, if the ferments necessary to excite nitrification lie at the bottom of the stream their influence upon the water will be thus aided by the current, but that the agitation of the water alone is of any particular benefit, has not been supported by a shadow of proof. In several Canadian rivers, whose course was marked by rapids and waterfalls, samples were taken at points above and below, without showing any alteration in the number of bacteria present which could be ascribed to the action of the waterfall or rapid. It is of interest also, in this connection, that chemical analyses, made a few years previously in the same localities, failed to show any improvement in the water consequent upon the "aëration" which was suffered to take place in rapid currents. The term, aëration of water, is one which seems to have come into existence through a total misconception of the real nature of the processes by which the oxidative and nitrifying phenomena in water are carried on.

How are we to account for the disappearance of bacteria from natural bodies of water at rest? Undoubtedly the simple sedimentation or sinking of the bacteria themselves, or of the suspended particles to which they are attached, plays an important part. Water is found to free itself, to a large extent, of suspended organic matter, in passing through these natural "settling basins," and it is reasonable to suppose that the bacteria tend to sink to the bottom. This could only apply to non-motile forms, and the majority of organisms found in water have independent motion. Experiments by Wolffhügel, Cramer, and Hueppe, of allowing water to stand in tall jars or tubes, showed that in some cases an apparent sinking of the bacteria to the lower strata really took place, while in others it did not. Gärtner experimented with motile and non-motile organisms in a similar manner, using pure cultures instead of unsterilized water, and found that in no case was anything corresponding to natural sedimentation obtained.

A point upon which too little stress appears to be laid is that, under natural conditions, the apparent sedimentation *is accompanied by a great reduction* in the number of bacteria present, while in the experiments an increase was usually observed. If the bacteria, or a large proportion of them, really sink to the bottom of standing bodies of water their numbers with increasing depths would certainly show a uniform increase. This is not the case. A few observers have at times noted that the number near the bottom of reservoirs, ponds, etc., is greater than at the surface (Currier, Wynter-Blyth, Cramer and Fol); but on the other hand, the results of the majority of observations show that this is the exception and not the rule. The writer was able, by means of a special apparatus, to examine the water at different depths in the Montreal reservoirs, and in some Canadian lakes and ponds, and found that in almost every instance the number near the bottom, at depths of twenty-five to fifty feet, did not exceed that at or near the surface. A progressive increase with the depth was never observed. The only instance in which the water at the bottom of a pond was found to contain notably more bacteria than were present at the surface, was that of a mill-pond, where the bottom was extremely foul and full of débris.

In the case of the Spree at the Havelsee (when the river above Berlin contained 8,950 bacteria per c.c., which number rose to 190,000 below the city and above the lake; while after passing through the lake the number fell to 9,200, showing that the water had been freed from the same number of organisms by which it was polluted in passing through the city), these polluting forms were not the bacteria peculiar to water, but those inherent to sewage and household water, street drainage-soil, and presumably pathogenic forms; and it is highly probable that those forms not natural to water would disappear more rapidly than the water bacteria proper.

Gärtner sums up the influences which may be supposed to act on the water in this instance as follows:

1. Sinking of non-motile organisms and spores of motile bacilli.
2. Spontaneous sinking of bacteria attached to suspended matter.
3. Artificial precipitation by substances used to purify the water.
4. Dying out of forms other than the water bacteria.

The precipitation of obnoxious substances from water by artificial means is a subject which will be referred to elsewhere (p. 1011). Apart from that, the above explanation seems too much dependent on passive and mechanical agencies to meet the facts of the case. That a constantly flowing stream of water, highly polluted, can in this way undergo such phenomenal improvement in passing through a shallow little lake about six miles in length, seems hardly credible, unless some more active agencies are in operation.

What calls for special comment is that in spite of the precipitation constantly going on, as revealed by the physical clearing of the water, the deeper layers of the water contain practically no more bacteria than those near the surface. Further, as this condition remains constant year after year, it seems inevitable that something connected with the sediment itself, or with the bed of the stream, is the agency most active in maintaining a pure condition of the water. If we suppose that some biological or chemical factor is present in the water (and most abundant at the bottom) by which bacteria coming within range of its influence are destroyed, we have an explanation of the fact that water near the bottom of a mass of water, where sedimentation is constantly going on, often contains fewer bacteria than water near the surface.

It seems more rational to seek the explanation of the self-purification of waters more on biological or chemical grounds, and less on mechanical grounds.

What is the nature of the agency which causes bacteria to disappear so rapidly from standing bodies of water? This question can only be answered imperfectly at present. Our positive information on this subject is due chiefly to Miquel, who studied biologically the behavior of pure and impure waters on being allowed to stand. As has already been stated, all waters, on standing in vessels or flasks, show a marked and rapid rise in the number of bacteria present, consequent upon the multiplication of the germs contained in them. Thus, a sample of Montreal water, which immediately after its collection gave fifty-eight colonies when sown in gelatine, increased on subsequent examination as follows:

	Per c.c.
After 2 hours	96
" 6 "	168
" 8 "	390
" 10 "	3,200
" 12 "	15,460
" 24 "	62,000
" 48 "	480,000

This increase of bacteria in waters standing *under artificial* conditions has received more or less attention at the hands of almost everyone who has worked at biological water analysis. The phenomenon has been thoroughly investigated by Bolton, Wolffhügel, Frankland, Cramer, Hueppe, and Miquel, and all observers agree in stating that after a gradual rise to many hundred thousand (usually one or more millions) bacteria per c.c. the number gradually subsides with repeated examinations, until, in samples taken some months or years after the first examination, bacteria may be almost absent. Miquel alone has given anything like a rational explanation of the causes determining the secondary decrease in number following the primary increase. He considers it likely that the bacteria are poisoned by their own products, and so prevented from further increasing. With that vivid scientific imagination characteristic of the great French scientists, he calls the process "auto-infection" of water, and considers it analogous to the processes observed in infectious diseases. Starting from the point of view that it is the products of bacterial life which check the further increase of bacteria, when it has reached a certain point, Miquel formulated the view that this substance would be more abundant in waters which were strongly contaminated, than in those which were pure: and therefore that water originally pure would possess less power of resistance to this auto-infection than impure water.

The observations published by Miquel certainly bear out his view, though, so far as I am aware, they have not been controlled in the work of other observers. Miquel found that the waters of the Vanne, St. Laurent, and the Dhuis (which he selects as relatively pure waters at the time of examination, since the number of bacteria they contained was well below 1,000 per c.c.) showed an early and rapid rise in the bacteria curve when allowed to stand, followed by an early and rapid fall, as indicated in the diagram.

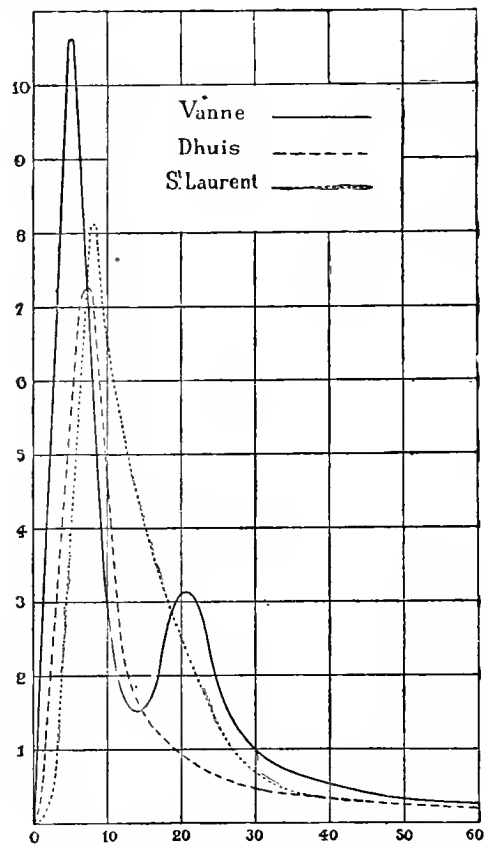

FIG. 665.—Auto-infection of Pure Waters. (Miquel.)

The ordinate lines denote a scale in units of 100,000 bacteria per c.c., and the abscissæ mark the days.

On the other hand, water of the Marne and Ourcq, which are impure waters, containing 60,000 per c.c., show a much more gradual rise, which only becomes well marked by the time that the number is falling in purer waters, but which is much more persistent. This capacity of resistance in impure waters is thought by Miquel to depend upon certain substances analogous to the defensive proteids or bactericide substances now known collectively by common consent as alexins. At the same time it must not be overlooked that the bacteria found in impure water, especially that contaminated by sewage, do not belong to the class which rapidly increase in water, and no information is given by Miquel as to which species gave rise to the increase.

The curves taken by the impure waters of the Marne and Ourcq are shown in Fig. 666, and for comparison

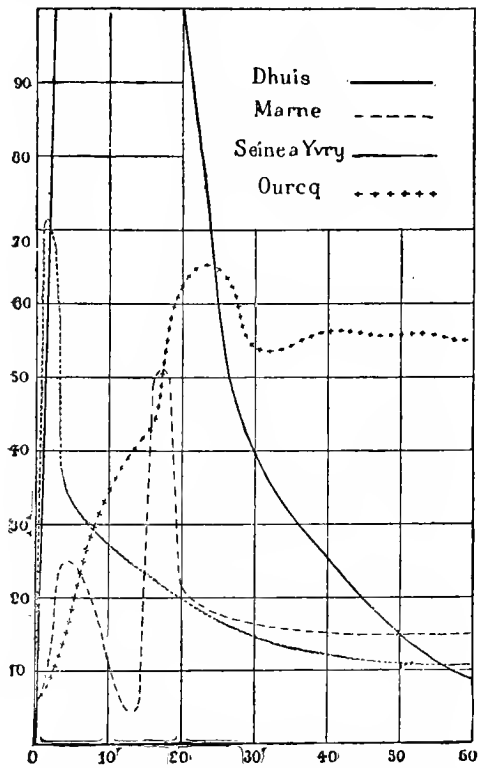

FIG. 666.—Auto-infection of Impure Water (Miquel).

curves are shown of the relatively pure waters of the Seine and Dhuis, at a time when through temporary contamination the bacterial richness was about the same as the permanently impure water. All the cultures were kept at a temperature of 30° C. The scale is in units of 1,000 bacteria per c.c.

It must be admitted that M. Miquel is rather unfortunate in his selection of types of pure water. The average number of bacteria present in the water throughout the year is stated to be as follows: Vanne, 800 per c.c., Dhuis, 1890, Seine at Ivry, 32,500. These waters certainly do not strike one as being particularly pure, especially when we consider that the best of them, the Vanne, at times contains as many as 14,000 bacteria per c.c.

Miquel does not rest his assumption of the presence of a bactericide or restraining substance in water on the above grounds alone, but has endeavored to isolate the substance. By introducing cultures of bacteria capable of developing in water, into various water samples, he found that, while at first this led to an increase in the number present, later on no such increase took place; the water thus having become, as he expresses it, *immune* or capable of resisting the process of auto-infection. That this immunity was not solely dependent upon the *abstraction* of substances furnishing nutrition to the bacteria, was shown by the fact that, after boiling, it again became susceptible to auto-infection, and afforded a good medium for the growth of water bacteria.

Acting on the assumption that the substance rendering the water immune or *infertile* was destroyed by boiling, M. Miquel tried to free the water from its bacteria by filtration, and by distillation *in vacuo* at the temperature of 30° C. By means of the ingenious apparatus shown in Fig. 667, samples of water were evaporated at this temperature from the dish *V* and the vapor, condensing upon the surface of the flask *B*, through which a current of cold water was kept circulating, dropped as water into the sterilized bottle *F*, in which, by reason of its narrow neck, very little evaporating surface was offered. The interior of the bell jar, and the outer surface of *B*, were sterilized previous to use.

The water collected in *F* in this manner, when obtained from samples of impure water, was found to be, not only sterile and free from bacteria, but *infertile* and incapable of nourishing them, a fact considered by Miquel to establish the existence of a restraining substance in solution in this water. Miquel and Wada published several experiments upon water of this description, in which it was found that bacteria introduced into it were found to disappear after the lapse of a few days, while in control experiments, where sterilized distilled water was employed, a growth of from one to six millions per c.c. was noted.

No statement has been made as to the chemical composition or properties of the substances which render water infertile. The presence of substances of this nature in natural waters would appear to afford a most rational explanation of the great reduction of bacteria in large bodies of natural water. That the formation of these substances is connected in some way with the bed of the stream is rendered probable by the fact that, though sedimentation must apparently be constantly going on, the lower strata of water do not show more bacteria per c.c. than that near the surface—possibly because the restraining substances are more abundantly present near the bottom. It is difficult to avoid associating the formation of these products in water in some way with the nitrifying organisms which, we know, form a sort of film at the bottom of standing water, but in the absence of any direct experimental evidence on this point we are not in a position to form any definite conclusions.

The aëration of natural waters depends upon the amount of dissolved or suspended air or oxygen present. Apart from purely mechanical causes, this is regulated by the circulation currents going on in the water as a consequence of heating and cooling. The oxygen furnished by the aquatic plants is essential to a normal condition of the water. At great depths and in stagnant waters, the amount of dissolved oxygen has been shown to be very small, and this must have a modifying influence upon the number and kind of bacteria present. It would be expected, *prima facie*, that in deeper waters *anaërobic* bacteria would predominate, but in the recent examination of the deep water of the Gulf of Naples by Russell, such was not found to be the case. The distribution of anaërobic bacteria in water has as yet received but little attention, and requires far more careful study, since anaërobic bacteria were long since shown by Pasteur to be active putrefactive agents.

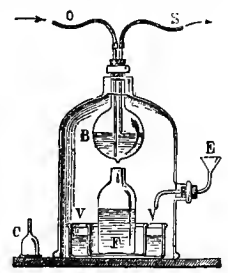

FIG. 667.—Miquel's Apparatus for Obtaining Infertile Water by Distillation at 30° C.

An increased number of bacteria, observed at times near the surface of waters, has been thought to be due to the greater abundance of oxygen there.

The cycle of bacterial life in natural waters has recently been studied by Migula, Karlinski, and di Mattei, keeping up as far as possible the natural conditions, but maintaining a low temperature and a constant current in the samples, and in one instance by lowering a sterilized vessel into a natural spring and allowing it to remain there while the tests were being carried on. Under these conditions the increase of water bacteria (auto-infection) was comparatively trifling.

Relation of Bacteria in Water to the Amount of Nutrient Substances Present.—Gärtner, after an exhaustive review of the available literature on this subject, comes to the conclusion that no constant relation exists between the number of bacteria in a water and the amount of nutrient material it contains. According to Naegeli,

the chemical composition of bacteria includes not only carbon, hydrogeu, oxygen, and nitrogen, but also sulphur, phosphorus, potassium and calcium, and other inorganic elements. The nitrogen and carbon can only, be stated, be taken from pre-existing organic carbon and nitrogen compounds. Bolton found that certain bacteria (Micrococcus aquatilis and Bacillus erythrosporus) were capable of unlimited development in water in which organic matter was not present in quantities sufficient to be estimated by chemical tests. He reckoned the weight of twenty million of these bacteria to be only $\frac{1}{100}$ of one milligram. Bacteria vary greatly in regard to the amount of organic matter required to enable them to develop: some requiring, apparently, none at all, while others (notably the pathogenic microbes) only increase when an appreciable quantity of organic matter is present. Cramer found that by diluting nutrient gelatine with sterilized distilled water, so as to bring the amount of organic matter in three samples to $\frac{3}{100,000}$, $\frac{1}{100,000}$, and $\frac{1}{1,000,000}$, and introducing water containing 312 bacteria per c.c. into each, the increase in bacteria was to some extent directly proportionate to the amount of organic matter present; but that even the most attenuated solution contained 3,256,000 bacteria per c.c. at the end of four days. The extent to which bacterial *cannibalism*, so to speak, takes place under these conditions has not been determined. Bolton found that the presence of 6.7 parts of nutrient material per 100,000 was necessary for the increase of typhoid bacilli, and 40 for the cholera vibrio. Of all substances peptones are the most potent in inducing bacterial growth; after these come albumin and sugar, then leucin or tartrate of ammonium with sugar, then albumin, and ammonia salts (Naegeli). The importance which organic matter bears to bacterial increase in water depends chiefly upon whether the bacteria contained in it are of a kind which requires the presence of these substances for their development. From the above it follows that waters most rich in bacteria are not necessarily those which give the highest amount of organic matter upon chemical analysis.

Chemical Changes Produced by Bacteria in Water.—It is difficult to determine exactly the part played by bacteria in the chemical phenomena observed in water. We know that, generally speaking, the bacteria produce metabolisms similar to those resulting from animal aquatic life, changing albuminoids into extractives, and tending to absorb and combine with free oxygen. While resembling plants in possessing the property of assimilating nitrogen from ammoniacal compounds (Cohn), they are unable to obtain their carbon from carbonic acid. Moreover, the anaërobic forms do not liberate free oxygen.

Nitrification.—Although the bacteria found in water are capable of splitting up nitrogenous bodies into derivatives which are ultimately oxidized, they are themselves incapable of completing the process, and appear to deal only with the preliminary stages. The main oxidation processes in water may be summarized as the series of steps by which albuminoid and ammoniacal substances are transformed into nitrites and nitrates. In the formation of nitrates or nitric acid out of albumin or protein there are four distinct stages, which may be considered as perfectly distinct: (1) proteid; (2) ammonia; (3) nitrous acid; (4) nitric acid. The chemical nature of the processes known as "self-purification" of water is practically the change of proteids and ammonias into nitrites and nitrates. The former (1 and 2) may be regarded from a hygienic standpoint as relatively dangerous, and the latter (3 and 4) as relatively safe components of a water, in so far as they indicate that unstable compounds have been changed into stable ones, though of course the detection of nitrites and nitrates in a drinking-water indicates in itself the existence of an undesirable contamination. The existence of nitrites and nitrates in water, therefore, though bad in itself, still shows that the oxidation or nitrifying agency is at work in removing the contaminating materials. The principal source of nitrites and nitrates in water being sewage, which always contains large amounts of chlorides, besides albuminoids and ammoniacal nitrogen, the degree of oxidation which has taken place can be inferred from the proportion to the chlorides, since the chlorine is an element which does not undergo changes through nitrification.

Though the nitrification phenomena have long been recognized in waters, our accurate knowledge on the subject has been derived from the study of these processes in soil by Gilbert and Lawes, Warington, Schloesing and Münz, Frankland, and especially Winogradsky. It was established by Schloesing and Münz that nitrification must be the result of the action of some organisms, and as the process was so universal in waters, the water bacteria were naturally looked upon as being the possible cause of the phenomenon. It was shown that nitrification in soils could be arrested by agencies capable of checking bacterial life, such as boiling, saturation with chloroform, etc., but for a long time all attempts to isolate an organism capable of producing nitrification were unsuccessful. Frankland, after testing the powers of the bacteria typical of water, found that these were not only incapable of nitrifying, but actually produced a reduction of nitrates to nitrites and ammonia, so that the action of the bacteria not only was not the cause of nitrification, but probably, under natural conditions, helped to mask it.

Heraus, in 1886, though the fact has not been generally recognized, undoubtedly worked with pure cultures of nitrifying organisms, and also showed that a species of bacteria exists which is capable of obtaining its nourishment, and constructing its tissue, from carbonic acid and ammonia. Heraus, however, was mistaken in ascribing nitrifying powers to a number of well-known bacteria, bacillus anthracis, etc.

After years of patient labor, Winogradsky, Warington, and P. Frankland succeeded in 1890, independently of each other, in isolating the nitrifying elements and obtaining them in pure culture. In America, E. O. Jordan had also arrived at the same end by the time the results of the European investigations were published. The method at first employed was that of adding small quantities of soil, which had been shown to possess nitrifying properties, to sterilized fluid containing ammoniacal and earthy salts—phosphate of potassium, sulphate of ammonium, carbonate of magnesium, sulphate of magnesium, chloride of calcium and carbonate of sodium, being used in varying combinations and degrees of dilution. The process was most active at a constant temperature of 30° C., but was observable between 12° C. and 40° C.

At the end of about ten days the ammonia in the solution disappeared and nitrites were abundantly present, with or without traces of nitrates. Later on, the nitrates increased, and in some cases the nitrites entirely disappeared, having been converted into nitrates. Upon adding fresh quantities of ammonia to the solution it was found in the same manner to be converted into nitrites and nitrates.

By introducing small quantities of these culture liquids into fresh sterilized solutions of ammonia and earthy salts the same course of events was observed, and in this way the cultures could be passed through a number of successive generations. It was found, however, that in these secondary cultures the process did not always go on to the formation of nitrates, but sometimes stopped at the nitrite stage. In these cases it was still possible to induce the formation of nitrates, by adding a fresh dose of the original nitrifying earth or some of the earlier cultures.

This observation led to the inference that two separate fermentations were involved, each depending upon the action of a distinct micro-organism. That is to say, that one *nitrous* organism existed, capable of forming nitrites out of ammonia, while the oxidation of nitrites to nitrates was effected by a separate and distinct *nitric* organism. That both were present simultaneously in the earth originally employed, was shown by the fact that this substance was found capable of completing the process when the organisms present in the daughter-culture failed to do so. It was subsequently learned that the nitric or-

ganism does not flourish vigorously until the ammonia has, for the most part, disappeared, and its optimum is reached in solutions containing nitrite without ammonia. The failure of daughter-cultures to produce the nitric fermentation is due to the seeding of the secondary cultures being completed when the nitrous fermentation was at its height and before the nitric organism had had favorable opportunities for growth. In this way the nitric organism becomes gradually climinated from the culture fluids.

Isolation of the Nitrifying Organisms. — The above results were obtained in large part by working with mixed cultures containing not only both of the nitrifying organisms, but also a certain number of bacteria originally introduced with the earth, and which formed the requisite nutrient materials for their existence in the saline fluids employed as culture media. Numerous attempts were made to isolate by the gelatine and agar plate method the nitrifying organisms, but without success, as for some reason these microbes refuse to grow at all in organic gelatinous substances.

Failing this, recourse was had to a much older method, that of dilution of the cultures sufficiently to obtain samples containing the nitrifying organisms, but free from bacteria. By greatly diluting the impure culture fluids with the sterilized nutrient saline solutions, cultures were obtained in sterilized glass-stoppered bottles (carefully guarded against infection from dust, etc.), which, while capable of setting up the nitrifying changes, were found free from bacteria by the gelatine plate process. In this way pure cultures were without great difficulty obtained, which formed nitrous acid in ammoniacal solutions, and though the isolation of the nitric ferment was a much more difficult matter, it was likewise successfully accomplished.

The organisms, when isolated in this manner, were found to exist in the form of a jelly-like layer adhering to the sides and bottom of the glass (Warington), an appearance long familiar to persons engaged in water analysis, but the significance of which was never before suspected. This substance forms abundantly at the bottom of streams and ponds, and though experimental proof of its nature is yet wanting, there can be little doubt that it furnishes the active agent in the nitrification of water under natural conditions.

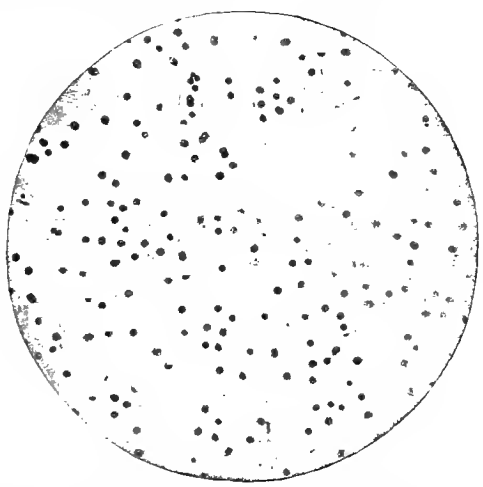

Fig. 668.—Microphotograph of the Nitrous Ferment, B. Nitrosus, × 1,000 (Winogradsky). N.B. The culture does not appear to be perfectly pure, as some short, slender bacilli are seen in the field.

Accounts of the morphological characters of the nitrifying substance under the microscope, as described by different independent observers, show a remarkable unanimity. By all, the organisms are described as small oval rods 1.5 μ in length and 0.5 μ in width: in addition to which, rounded disk-like bodies occur having a diameter of 1.5 μ to 2 μ. The fact of two morphologically distinct organisms being described is what we might expect from the fact that two different fermentations exist. Winogradsky has shown that in solutions in which a purely nitrous fermentation was going on, the larger

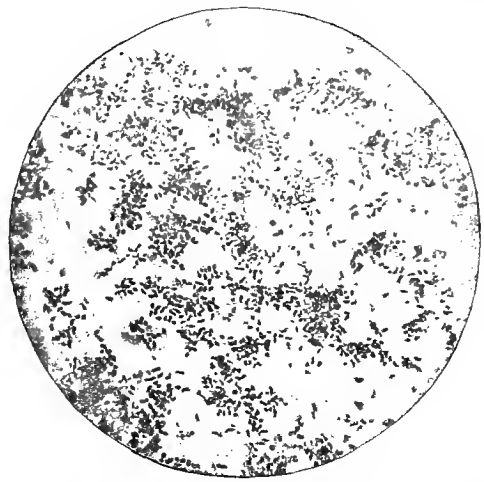

Fig. 669.—Microphotograph of the Nitric Ferment, × 1,000 (Winogradsky).

round bodies were alone present (Fig. 668), while in the purely nitric fermentation the smaller rod-shaped organisms alone were found (Fig. 669).

We have, therefore, nitrous and nitric periods of fermentations, each perfectly distinct and presided over by a separate organism, though under natural conditions both processes go on simultaneously, and the nitrous period is merely transitory. The nitrifying organisms are stained feebly by all the aniline dyes. They do not stain by Gram's method. The staining is best accomplished by allowing an extremely dilute, almost transparent solution of malachite green to act on a cover glass specimen (dried and fixed in the usual manner) for at most half a minute. The cover glass is then washed and stained with an equally dilute watery solution of gentian violet. The nitro-organisms are stained intensely by this means, and the intervening gelatinous substance remains colorless. The use of mordants, etc., is liable to lead to a granular precipitate and to staining of the intercellular mass.

Although the nitrifying organisms were undoubtedly obtained in pure cultures by the dilution of liquids, their ready isolation and accurate study were first made possible by a most ingenious plan, employed by Winogradsky, who obtained an inorganic gelatinous substance by the use of soluble silica (water glass) as recommended by Kühne, in which the organisms grew readily. The details of this procedure are described under Methods (p. 1017).

The exact relation in which these organisms stand to the bacteria proper is not yet definitely settled, but they have the general morphological characters of bacteria, and probably might be included under the group of pleomphic bacteria. Although the nitrous organism is of a distinctly rounded form, I shall provisionally refer to them here as Bacillus nitricus and Bacillus nitrosus, respectively, as the name of nitromonas, which has been applied to them, has the disadvantage of confusing them with the animal genus Monas. Winogradsky has suggested that they should be considered as a new *genus*, "*Nitrobacterium*," but has not yet brought out any convenient nomenclature to distinguish the nitric and nitrous species. A point of special interest in connection with these remarkable organisms is that, like plants, they are capable of assimilating their carbon directly from CO_2 or the inorganic carbon compounds. This physiological peculiarity certainly makes it necessary to distinguish them from the bacteria proper.

The process of nitrification has been carefully studied in connection with sewage filtration by the Massachusetts State Board of Health, it being found that when nitrification set in a very marked decrease in the number of bacteria took place.

Of the remaining chemical changes induced by the bacteria of water, we know, unfortunately, very little. As already stated, many of the water bacteria are capable of reducing nitrates to nitrites, but to what extent this takes place in natural waters we are at present unable to state. It is also possible that saprophytic organisms producing definite fermentations under artificial conditions, may sometimes act in a similar way under natural conditions, provided the needful food-supply, temperature, etc., are forthcoming.

The life processes of the anaërobic bacteria in water, have not yet received accurate study. As a rule, anaërobic bacteria are very scantily represented in water, forming less than five per cent. of the total number of species met with in pure water. In impure waters, on the other hand, the numbers appear to be relatively larger. Miquel found fourteen per cent. of anaërobic bacteria in the water of the Seine at the Chaillot pumping-station. The proportion of anaërobic to aërobic bacteria is probably regulated by the amount of dissolved oxygen in the water. Stagnant water should, in the writer's opinion, be considered as one in which the process of oxygenation is materially below the normal. Such waters are favorable to putrefactive changes by the anaërobic bacteria, and therefore, in all cases where stagnation is suspected a numerical estimation of the anaërobic forms, as well as the aërobic, is of special importance. Owing to the imperfection of the methods of anaërobic culture this matter has been almost uniformly neglected in water analyses, as far as quantitative work is concerned; but, with improved methods we may soon hope for more exact information on the subject.

Various forms of the saccharine alcoholic fermentations have been artificially produced by bacteria obtained from water, but we have no evidence to show the extent to which these fermentations take place under natural conditions.

Winogradsky, some years ago, described two specific chemical changes due to the action of certain bacteria. These were, (1) the oxidation of ferrous oxide in water containing traces of iron, leading to the deposit of ferric oxide in the protoplasm of a certain species of leptothrix, which constitutes the slimy, reddish scum and sediment so often found in ferruginous waters; and (2) the oxidation of sulphides, in sulphuretted mineral waters, into sulphuric acid by the action of a genus of Beggiota. (*Thiothrix.*)

Petruschky has attributed the alkalinity of certain waters to the preponderance of fluorescent bacteria, which he found to produce alkaline fermentation.

The nature of the inhibitory substances shown by Miquel to exist in his infertile waters, has not yet been demonstrated, as they were obtained in water which had been distilled at 30° C.; they are volatile and possibly aromatic in nature.

The general tendency of the changes in water due to biological causes may be outlined in the following table:

Agent.	Nature of Action.	Original Substance.	Resultant Product.
Plants.....	Reducing.	CO_2, NH_3, HNO_3.	Oxygen; proteids.
Animals.....	Oxidizing.	Albuminoids.	CO_2, Extractives.
Bacteria.....	Oxidizing.	Albuminoids.	Ammonia.
Bacteria.....	Reducing.	Nitrates.	Nitrites.
Nitrobacteria...	Oxidizing.	Ammonia, Nitrites.	Nitrites, Nitrates.

It must be understood, however, that the general tendency is toward oxidation and that plants indirectly aid in oxidation by liberating the necessary free oxygen.

Contamination of Waters.—From a sanitary standpoint the most important sources of contamination of water-supplies are those arising from the influence of human habitation and industry, so that, as a general rule, the degree of contamination of water is directly proportionate to the amount of population in relation to the area of the water-shed and the volume of water. In densely populated districts watered by small streams, the pollution of natural waters is usually sufficient to unfit them for drinking purposes without previous purification by artificial means. The contaminating substances are divisible into three classes: 1, the waste of industrial establishments; 2, household waste; and 3, sewage proper, containing excrement. The chief danger lies in the last class, and is owing to the risk of spreading infectious diseases. Other household and kitchen refuse is less dangerous because less likely to contain the germs of disease, but from its greater bulk is likely to produce a more obvious state of pollution in the water, and to render it unwholesome for drinking, even though less liable to spread specific infectious diseases. Factory waste, such as flows from dye-works, and other establishments where chemicals are employed, though the least dangerous of all, is likely, from its abundance and disagreeable physical characters, to impair the quality of the water.

The degree of danger to drinking-water supplies from any sources, depends less upon their actual extent than upon the degree to which they are susceptible of being controlled and regulated by the sanitary authorities. If factories can be compelled to obviate, by precipitation or other means, the objectionable features in their waste water when this enters some source of drinking supply; if the household waste is separated from the more dangerous parts of the sewage, and the latter dealt with separately by precipitation or filtration upon a sewage farm, it is obvious that the contamination of water passing through a town, even when of large size, must be much less than that created by a smaller town where the sewage and drainage are not properly looked after. The great safeguard against contamination of water-supplies, both small and large, lies therefore in the direction of keeping, as far as possible, sewage and drainage from directly entering the water.

A recent statement by von Pettenkofer that the bad effects of sewage rapidly disappear from water, has met with general dissent.

The effects of the drainage of towns upon water was well shown in Berlin, in 1881, where the number of bacteria per c.c., which above the city was 82,000, rose to 1,800,000, 4,480,000, and 10,180,000 in consequence of its passage through it. (Koch.) These numbers have been considerably reduced in consequence of proper supervision having been exercised, so that now, even in the worst places, the number of colonies in Spree water does not exceed a few hundred thousand per c.c. In Paris a similar deterioration was observed in the water of the Seine by Miquel, who showed that, while the water above the city only contained 300 bacteria per c.c., upon entering the city this number rose to 1,200, and further on, after receiving sewage, to 200,000 per c.c. The most marked change was noted below the floating wash-houses, which line the banks of the river in places, as the river water below one of these actually contained 26,000,000 bacteria per c.c., or over four times the number found in the sewers themselves.

This pollution of the water is not only dangerous, in that it indicates a dirty condition to be present, but still more because that condition is due to a cause which might be associated with the germs of infectious disease. In estimating the degree of danger from a polluted water, the cause of the contamination must be borne in mind. While a marked rise in the number of bacteria might have no special significance if due to the washings of a heavy general rainfall carrying alluvial soil into the water, a much slighter rise, distinctly traceable to sewage, would indicate a far greater danger.

In the case of rural districts it is necessary to see that wells and springs are placed where the drainage and washings from privies, cesspools, barnyards, etc., cannot possibly enter them. And the water-shed of a tract of country supplying water to a neighboring city should be carefully inspected to see that no nuisances of this de-

scription exist in dangerous proximity to tributary streams or aqueducts. A recent commission, appointed to overlook the Croton water-shed, which furnishes the water to New York, stated that over four thousand nuisances of this description existed.

Probably the most important duty in protecting water from contamination by cities and towns is the separation of the dangerous parts of the sewage, and their disposal by means of a sewage farm. This has now been carried out in the case of most of the larger European cities, usually by means of large collecting cesspools of iron, from which the contents are pumped out at regular intervals into iron tanks and carried out to the sewage farm. A complete duplicate system of drain-pipes would be still better, but as the bulk of the fecal matter is not excessive it can readily be handled by the simpler means of pumping into portable closed tanks. When this is carried out the improvement in public health, especially as regards freedom from typhoid, is very marked. The death-rate from typhoid in Munich, falling from 100 to 300 per 100,000, down to 10 to 20 per 100,000, being probably largely attributable to this cause, though an improved water supply was introduced at the same time.

Artificial Purification of Water.—It may be laid down as an axiom that a water-supply should be, if possible, taken from a source which would render it above suspicion; but where this cannot be done, then the next best thing is to purify it artificially before consumption.

The means employed to purify waters biologically are: 1, sedimentation; 2, precipitation; 3, filtration; 4, sterilization, or in some cases a combination of several of these.

1. *Sedimentation.*—The beneficial effects upon natural waters due to standing, have already been pointed out, and a marked improvement can also be effected in the case of many supplies by the construction of proper settling basins and reservoirs, in which the process of sedimentation is allowed to take place before the water is distributed. As it was shown that, in all probability, the great reduction in the number of bacteria taking place in natural bodies of water at rest is due, not simply to the mechanical action of gravitation, but to biological causes, in which the nitrifying organisms possibly play an important part, care should be taken that the floor of settling basins consists of material capable of inducing nitrification. For this, sand or gravel beds are perhaps the best, but in any case the sediment falling from the water itself probably furnishes the requisite materials. The idea that the beds of settling basins and reservoirs should be formed of cement and washed clean at frequent intervals is founded on a totally erroneous idea of the agencies by which water is purified, since, undoubtedly it is this very sediment, which hydraulic engineers are desirous of removing, that is the chief agency by which water is purified.

As to whether reservoirs, etc., should be covered or not, is a question depending upon whether the degree of exposure to contamination by dust is sufficient to counterbalance the benefits from access of sunlight. The requirements for an ideal settling basin are, therefore, (*a*) a bottom containing nitrifying material, (*b*) a situation protected from dust but open to sunlight, (*c*) sufficient depth to secure the benefits of gravitation of the suspended material, but not enough to interfere with the circulation and oxygenation in the deepest parts, (*d*) separate inlet and outlet, (*e*) sufficient capacity to allow that the daily consumption does not exceed ten to twenty-five per cent. of the volume of water which it is intended to settle, (*f*) provision for cleaning occasionally.

In some reservoirs it has been noted that an increase of bacteria takes place subsequent to standing. This is especially noticed in filtered waters, and seems clearly due to the absence of the conditions conducive to nitrification. The beneficial effects of even partial settling were well shown in the case of the Montreal lower reservoir, containing eighty million gallons (daily consumption of water from reservoir being ten to twenty per cent.), which showed on the average less than one-fourth as many bacteria as were found in the aqueduct supplying it, in a series of examinations extending over an entire year. The benefit of settling is most marked in the case of those waters which have naturally good keeping powers, or where much inorganic matter is suspended. The growth of algæ, in some reservoirs and filtering galleries, causes considerable trouble, and more so in open than in covered basins.

2. *Precipitation* has until now been chiefly employed for the chemical purification of sewage, especially to remove and obviate the waste of factories. Artificial experiments with bacteria, on a small scale, by Krüger and others, gave somewhat unsatisfactory results. It was found that by means of such precipitants as lime and charcoal, the number of bacteria could be reduced by about ninety per cent., but that subsequently an increase took place. Wiebe and Wahl found that by the employment of the "Röckner-Rothe" apparatus, sewage containing 1,686,000 to 5,245,000 bacteria per c.c., only contained at the end of the process 34 to 178 per c.c. These results, brilliant as they seem, are more applicable to the purification of highly contaminated bodies like sewage than to ordinary water. The natural taste of the water also suffers by this treatment, and its increased hardness unfits it for certain purposes.

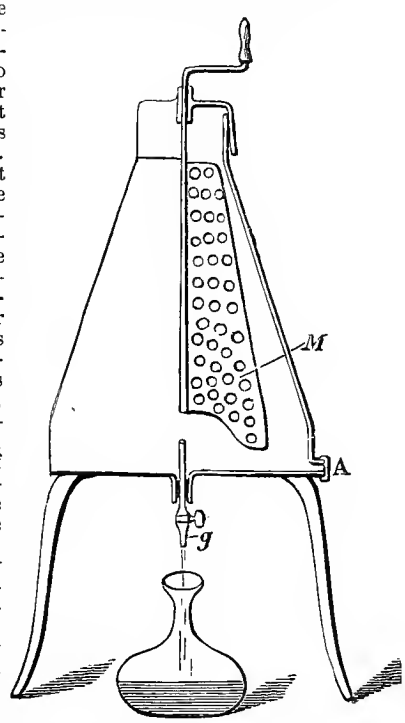

Fig. 670.—Babes's Apparatus for Precipitation by Alum. *M*, mixer; *g*, glass tap and tube; *A*, aperture for cleaning.

Of many other precipitating agents, probably, fragments of iron and minute quantities of alum are the most reliable and free from objection.

Babes has recently strongly urged for precipitation in households the use of alum, having found that by mixing alum with the water to be purified, in the proportion of 1 to 6,000, or 1 to 10,000, and stirring thoroughly, when the mixture is allowed to settle for a few hours a perfectly clear water can be decanted, having a pleasant, refreshing taste, and not only containing no bacteria at first, but remaining free from them even if allowed to stand in open vessels for several days. This water is found to be chemically free from alum, since the latter, when precipitated, forms an insoluble compound with the suspended matter. A simple and cheap form of apparatus, recommended by Babes, is shown in Fig. 670.

The chemical nature of the changes which occur here have not yet been explained. The most remarkable feature in connection with it is the tendency of the water to remain infertile, or in other words, to preserve its powers of self-protection against infection from without. This simple plan may be destined to come into extensive use in replacing the ordinary household filter, which, too often, is simply an abomination, tending in many cases to promote the objectionable features which it is designed to remove.

The great objection to all the customary modes of filtration is the increased susceptibility of the water to subsequent contamination, and it seems that a move in the

right direction is made by adopting a method which furnishes a water as capable of resisting auto-infection as natural waters are under natural conditions. In the absence of any experimental proof we must refrain from speculating as to whether this retained power of self-purification is due to the fact of the nitrifying elements being left intact, or to the retention in solution of the volatile protective substances whose existence in water has been established by Miquel. The behavior of pathogenic bacteria in water thus purified, would be worthy of study. Similar results can be obtained by the use of small quantities of chalk and sulphuric acid, or of sulphate of iron, but the quantities required are somewhat greater, and the decanted water is not always clear.

By means of suitable apparatus to secure thorough mixing and subsequent settling, these methods have been applied with considerable success to large water-supplies. Naturally, it is necessary to control their working by bacteriological tests, a matter too often neglected by the engineers and civic officials intrusted with the care of water-supplies; and the neglect of this scientific supervision is probably more to blame for failure of the methods in actual practice than to any inherent defects in the methods themselves.

Electricity.—Fermi has tested the action of electricity, and found that a marked diminution in the bacteria and other impurities of contaminated waters can be effected by means of an electric current. The mode of action appears largely dependent upon precipitation induced.

It has been suggested to employ electrolysis of saline solutions for the purpose of precipitating the organic and organized matter of the New York water supply (Edson).

3. *Filtration* is the means most commonly employed for cleansing impure water both in households and in large supplies. We have seen that, while the soil at the surface of the earth contains millions of bacteria per cubic centimetre, that taken at a depth of two metres is usually nearly or quite free from organisms, and that ground-water rarely contains any considerable numbers. As water is constantly percolating through the soil and setting up minute capillary streams, which extend in directions depending upon the forces of gravity and capillarity, it is remarkable that more bacteria are not carried to the deeper layers; and the fact that such is not the case is only to be explained by assuming that the soil itself is constantly acting as a vast universal filter, separating and retaining the innumerable bacteria at the surface, without permitting them to penetrate.

When sand is employed for filtration it is found that, in a properly working filter, most of the bacteria are retained in the upper few inches, but that when clean sand is employed a considerable number of bacteria pass through it and can be detected in the filtered water of the effluent. The number of bacteria which pass through depends largely upon the rate of flow, as determined by the pressure of water permitted. After a few days this number becomes much less, until few or no bacteria can be detected in the filtered water. Strange to say, this increased filtering power appears due to the mechanical action of the sediment itself, which, though swarming with bacteria, mechanically obstructs the pores of the filter in a manner not obtainable by the finest sand procurable. A properly acting filter is therefore neither more nor less than a dense bed of bacteria and slime, which so obstructs the pores of the sand as to prevent the passage of organisms. This obstructive substance is less composed of living than of dead and degenerated micro-organisms.

The efficiency of filtration can be readily estimated by comparing, by means of the gelatine-plate method, the number of colonies developing from a given quantity of unfiltered and filtered water.

The bacteria which appear in the effluent of filtered water are not, as a rule, the residue of those which entered, but, rather, are organisms which have been washed away from the deeper parts of the filter (Bertschinger), though it has been proved by working with cultures of easily recognized organisms, such as B. prodigiosus, that a certain proportion actually pass through and appear in the effluent (Fränkel).

The degree of efficiency of a filter in removing bacteria has been represented diagrammatically by Piefke as shown in Fig. 671, where the ordinate lines represent different levels in the bed of filtering sand; a, b, e, d, having a depth of 30 c. m. The distance from the abscissa h i, represents the number of bacteria retained in the water, and the curve k y l showing this number is seen to be reduced $\frac{5}{6}$ in the first 10 c. m. of sand, and $\frac{1}{10}$ in the second 10 c. m. The efficiency of the filter cannot be considered satisfactory until the curve k y l reaches the abscissa line h i, an effect which was usually attained at the end of fourteen days in the case of the filter at Berlin, upon a model of which the observations were made.

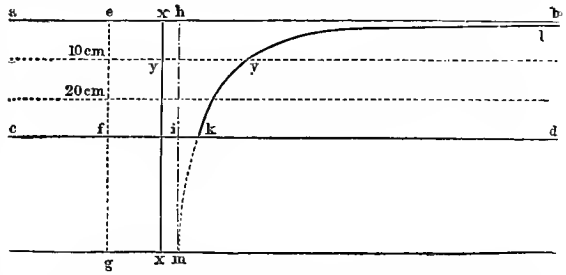

FIG. 671.—Diagram Expressing Efficiency of a Sand Filter (Piefke).

A sand filter which is working properly should yield a filtrate almost free from bacteria. As the bacteria which exist in the filtrate are not the same individuals which entered the filter, it is not quite correct to express the working of a filter in percentage, except with the reservation that the numbers given only show the relation between the two waters as regards richness in bacteria. In a good filter the bacteria in the filtrate only average, as a rule, ten per cent. or less of those in the unfiltered water: so that ninety per cent. of the total number of bacteria present disappear. This holds good of relatively pure waters containing only about 100 to 1,000 bacteria, but when the original water is notably bad in quality, and contains from 1,000 to 10,000 bacteria or upward per cubic centimetre, the beneficial effects of filtration become much more striking, so that ninety-five, or even ninety-nine per cent. of the number originally present may be removed. From this it follows that sand filtration is better fitted to render a poor water moderately good than to bring an already fairly good water up to the first-class standard. In other words, the numbers in the filtrate will be the same whether the original water contains 1,000 or 100,000 per cubic centimetre.

The extent to which a filter purifies water depends partly upon the construction of the filter bed, and partly upon the rate of flow. As a rule, the extent to which bacteria are removed is in inverse proportion to the rate at which the water passes through. It can be readily understood that the slimy masses of dead bacteria which clog the pores of the filter, are more likely to be washed out if the stream is rapid and the pressure great; while the living bacteria are more likely to pass through if the rate of flow is increased. Piefke and Fränkel were able, with a sand filter 30 mm. deep, by reducing the rate of flow in from 100 mm. per hour down to 30 mm. per hour, to reduce the number of bacteria in the filtrate from 60 or 100 per c.c down to 10 or 15 per c.c. (The rate of flow is calculated by the length of a column of water which would pass through a filter bed of corresponding area in a given time, and is for convenience reckoned usually in millimetres per hour.) The rate of flow which may be permitted in a given filter, depends also on the quality of water, as that containing a large number of bacteria requires to be filtered more slowly in order to attain the best results. Thus, while in the case of the relatively pure water of Lake Zürich it was found that a reduction of the bacteria to $\frac{1}{80}$ in the filtrate could

be attained with a rate of flow of 300 mm. per hour; with the water of the Spree, at Berlin, the same degree of improvement could only be attained by reducing the flow to 100 mm., or even 50 mm., per hour.

Previous sterilization by dry heat of the sand employed was not found at Berlin to improve the quality of the water furnished during the early period of filtration, but rather the contrary, and it was always necessary to reject the filtrate obtained during the first few days. Coarse sand was found more efficacious than fine, provided its grains were sharp. Previous to filtration the water should be allowed to stand for some time—one to two days—in settling basins, by which means the coarsest impurities and a large proportion of the bacteria are removed, and, the work of the filters being lessened, they do not require to be cleaned so often.

By the time a filter has begun to yield a good effluent the rate of flow has already begun to decrease, and the yield of filtered water becomes gradually less. The quantity may be increased somewhat by increasing the pressure, and several ingenious forms of apparatus have been contrived which regulate the pressure and keep the flow constant, acting upon the same principle as the governor of a steam engine. Ultimately the amount of the effluent becomes very small, and the filter is then said to be "dead" and requires to be cleaned.

In cleaning filters it is found that the surface of the sand is covered with a thin greenish-brown membranous pellicle from $\frac{1}{8}$ to $\frac{1}{16}$ of an inch in thickness (*Schmutzdecke*), beneath which the sand is found to be quite clean. Consequently, when this is removed with shovels or scrapers after the water has been run off, the filter is again rendered fit for use. (Piefke-Sedgwick.) It is this membranous layer which acts as the true filtering membrane.

The length of time during which a filter may be used without cleaning varies from two to three weeks in the summer to as many months in the winter. The entire bed of sand does not require to be renewed above once a year. After a filter ceases to furnish a pure water, its sand must then be removed and replaced by fresh.

According to Koch, chemical examination of water affords no indication of the efficiency of filtration, as the matters to be removed are suspended and not dissolved. He states that the effluent of each filter bed should be examined daily bacteriologically. The presence of over 100 bacteria indicates that something is wrong with the filter. The examination of the mixed effluent of all the filter beds may leave a dangerous defect in one or more individual filters undetected, as the total mass of water may not show the contamination. (Ztsch. f. Hyg., xiv.)

While the action of filters in removing bacteria from water, as tested by the state of the filtrate immediately after passing, is usually very satisfactory, there is a great tendency to subsequent growth of bacteria in the filtered water. On this account it is not well, as a rule, to store any very large quantity of water after filtration, but it is preferable to use it as soon as possible. The water during its purification is not rendered infertile, but its susceptibility to auto-infection is increased by the removal of the protective substances. Hesse, Wolffhügel, Riedel, and others have studied this phenomenon without very clearly explaining the causes which promote it. The chemical changes in water undergoing this deterioration seem to escape our present methods of observation. The curve seems in most cases to be that taken by pure water. For instance, an increase to 2,310,000 bacteria per c.c. in filtered water has been noted in the first thirty-six to sixty hours after filtration, subsiding to 2 per c.c. at the end of forty days (Dupont). That this increase forms an actual source of danger is highly improbable, as the organisms can only be the harmless water-bacteria, but at the same time it would obviously be better to obtain water in which no subsequent increase took place, and which resembled more in this respect natural bodies of water.

In stating that biological as well as mechanical processes are concerned in filtration through sand, it must be understood that the biological element is not simply the obstruction of the pores of the filter by the bacteria masses, but that chemical changes also take place in the water during filtration, which can be ascribed to biological agencies; and it is possible that the intelligent employment of these may effect future improvements in filtration. It must be borne in mind that a natural process of filtration is constantly going on in the soil, and so successful is this natural filtration that the ground-water is practically free from bacteria, and, with scarcely any exception, from all the organisms. This filtration is constantly going on, and yet the soil loses none of its filtering power. On the other hand, in the system of filtration employed for the water-supplies of London and Berlin there is a constant tendency for the filters to get out of order. The sand has to be cleaned and renewed at short intervals, and at first the water which comes through is too impure to be used for drinking purposes. Further, as the filtering material consists, practically, of a mass of dead and living organisms, it is evident that an objectionable element must be present in the filter before it begins to work efficiently, and that this element increases steadily until the filter becomes unfit for use.

Contrasting that natural filter, the earth, with the imitations employed by the water companies, we are at once struck with the fact that the former appears able to keep itself in order and does not deteriorate by use extending over a number of years, while the latter has to be kept in order artificially by constant watchfulness and attention, and becomes, even under the most favorable circumstances, inefficient at the end of a few weeks. It certainly seems worth while to study out the causes which produce such a vast difference between natural aud artificial filtration, and to see whether we might not take a lesson from nature and learn to filter as she does.

The first striking difference is that, while in artificial filtration the water supply is continuous, in natural filtration it is intermittent, depending upon the occasional falling of rain. Another difference is that in soil, under natural circumstances, the water is placed under conditions similar to those in which the nitrifying influences (organisms) work in the soil. Water percolating through a natural soil is constantly in the presence of the nitro-bacteria, and constantly having its ammonia changed to nitrites, and its nitrites to nitrates, or in other words, it is placed in a position to receive natural self-purification. When a water is purified in this way, under natural means and by natural agencies, it can be readily understood why this process should be continual and progressive, and why it should be able to look after itself without constant watching and manipulation, by changing and cleansing beds of sand, and so on. The reason for these self-contained powers of regulation is simply that the nitrifying organisms are the active agents, and as they live and increase through having material given them to nitrify, the more work they have to do, within reasonable limits, the better they are able to do it, provided always the surroundings are such as do not tend to check their action or destroy their vitality. Now, the one thing of all others which interferes with nitrification is a too great supply of albuminoid matter, which is not yet converted into ammonia or amides. Keeping this in view, it is easy to see that in the average filter the conditions present must, under nitrification, be very difficult, while under conditions resembling those which obtain in soil nitrification is facilitated and goes on by itself.

If the great purifying agency in water is nitrification, it seems unfortunate that, while attempting to purify water, we must commence by imposing conditions which render nitrification difficult or impossible. It would appear very desirable to adopt some method similar to that which goes on in the soil with such satisfactory results, rather than to insist upon trying to strain the water continuously by methods which give less satisfactory results and require so much attention. It might not be going too far to supplement Piefke's aphorism, that filtration is a biological process, by the statement that in the continuous sand filtration processes we adopt a method more liable to hinder than to favor it, and fail to take advantage of the natural methods by which the effect of

the biological agencies in filtration could be assisted and heightened.

The desirability of adopting, if possible, a system of intermittent filtration has led to numerous experiments being made to determine the nature of the water obtained by this means, and how much per day may be safely filtered through a given area of sand in order to obtain the best results. Frankland, in England, and the Massachusetts State Board of Health in America, have published the results of their investigations.

It is well known that the subsoil drains of sewage farms, which form a system of effluents to the filter beds, contain as a rule remarkably few bacteria, these having been removed by the soil. At Lawrence, Mass., a system of filter tanks was established for the purpose of obtaining accurate quantitative results in sewage filtration. These were filled with sand to a depth of three to five feet above a layer of rocks or cement; and some yellow loam was placed at the surface. The sewage was applied intermittently in small quantities at a time, and the observations upon the effluent were continued over periods of from two months to three years without changing or removing the filtering material. It was found that, by proper care, the filter at the end of three years' constant (intermittent) use was in perfect order, free from disagreeable odor, and capable of yielding an effluent containing few bacteria, only about .001 per cent. of the number in the original sewage, and which for the most part contained only 0.3 to one per cent. of the ammoniacal and organic nitrogenous matter present in the sewage.

These observers attributed these very satisfactory results to biological causes, namely, the burning or oxidation of the bacteria and organic matter by the agency of living organisms present in the sand. The conditions necessary to produce disappearance of the bacteria and nitrification were a temperature above 40° C. and an abundance of oxygen in the pores of the filter. By pouring or spreading the material to be filtered on the surface of the sand at intervals, the introduction of a constant supply of fresh oxygen was assured. The efficiency of nitrification in a filter was indicated not only by loss of albuminoid and free ammonia, but by increase in the nitrates. The reduction in the number of bacteria was generally directly proportionate to the completeness of nitrification, being less marked during the winter months, when the ammonia of the effluent averaged fifty per cent. that of the sewage, than in the summer, when it fell to between 0.2 per cent. and three per cent. The amount of sewage filtered averaged 50,000 gallons per acre daily. The reduction of bacteria during incomplete nitrification was always considerable, one per cent. surviving passage through the filter, but when nitrification became complete, a marked reduction appeared at once, so that only 0.08 to 0.03 per cent. appeared in the effluent.

Similar methods of intermittent filtration were experimentally tried with the water-supply of Lawrence, Mass., and the results obtained were quite analogous to those with sewage. It was found that, (1) the reduction in the number of bacteria corresponded closely to the completeness of nitrification; (2) that with suitable temperatures and a proper supply of air in the pores of the filter, marked nitrification was attained during the warmer months; (3) that even when nitrification was partially arrested during the cold weather, the improvement in the quality of the effluent, when compared with that of the inlet, was *fully as marked as could be expected from continuous filtration under the most favorable circumstances;* (4) the filter at the end of two years' constant (intermittent) filtration did not show any signs of deterioration; (5) the organisms other than bacteria were almost completely removed from the water; (6) the water of the effluent upon standing did not show that tendency to an increase of its bacteria by auto-infection characteristic of waters filtered by the ordinary continuous method. (For details, the admirable special reports of the Massachusetts State Board of Health for 1890 should be consulted, the work being reported with a care and thoroughness which leaves little to be desired.)

From the above experiments we have seen that it is possible, experimentally, to imitate successfully the natural filtration as it takes place in the earth, with the result of obtaining filters which gain, instead of losing, in purifying powers after years of use, and which yield a water comparable to the natural ground-water. The only drawback to the employment of this method in actual practice is that a much larger filtering surface is needed, or in other words, with plant of the same capacity a smaller yield of filtered water is obtained than by continuous filtration with periodical changing and cleansing of the sand.

To obtain the best results by the intermittent method, the quantity of water treated should not exceed 500,000 gallons per acre, per day. The filtration of the London, England, supply of 190,000,000 gallons per day, is obtained with a filtering area of 109¾ acres, giving 1,700,000 gallons as the average daily yield per acre, or more than three times what could be expected of the intermittent method. Even when it is considered that, of the total filtering area of London, over ninety per cent. has to be cleansed in the course of a month, and that a large proportion of the total area is always lying idle, it will be clear that for the quantity of water delivered by the intermittent system, the filter beds would require to have at least four times the area needed for continuous filtration.

What is expected of a filtering system is that it shall remove *all dangerous ingredients from the water*. That this is not done in actual practice has been shown experimentally by C. Fränkel, but that a dangerously polluted water, after thorough filtration, becomes a fairly safe one for a drinking supply, is a matter of universal experience. The extent to which filtration of a water removes the dangerous elements was shown by the appearance of a typhoid epidemic in Berlin during the winter of 1889. Owing to an unusually severe and prolonged frost, eight open filter-basins became useless, and the whole water-supply of that district had to be forced through five covered filtering galleries. Owing to the necessary increase in rate of flow, from 100 mm. per hour to 300 mm., the purification of the water became very incomplete, so that the filtrate contained for several months from 2,000 to 3,000, and at one time over 4,000, bacteria per c.c., instead of only 50 to 100 per c.c. The effect upon public health was that *in the portion of the city receiving this water* over three hundred deaths from typhoid occurred within a period of three months, at a season when usually but little typhoid was to be expected. The remainder of the city remained free from excess of typhoid during this period. As soon as it became possible, through the appearance of milder weather, to cleanse the filters, the number of bacteria in the water fell to 0 to 500 per c.c., and the typhoid mortality fell to its normal limits. A more striking proof of the occurrence of typhoid from drinking-water could not be asked for, though unfortunately the hygienic laboratories of Berlin made no special effort to ascertain if typhoid bacilli could be detected in the water during the period of the epidemic.

Koch has shown that the absence of cholera from Altona during the Hamburg epidemic in 1892 was due to an efficient filtration of the water, which was originally worse than that of Hamburg. In the winter of 1892–1893, when some of the Altona filter beds became frozen, cases of cholera began to appear.

A filtered water, though better than the same water before filtration, is not to be compared in hygienic value with a water obtained from a source which lies beyond the reach of pollution. In Vienna the most careful filtration of water obtained from the Danube still left the city with a most unenviable record for typhoid, while with the adoption of a supply from the neighboring highlands,* the mortality from this cause immediately decreased, although no other sanitary improvements of note in the drainage, etc., were carried out at the time. In Munich, formerly notorious for typhoid, although

* Unfortunately it appears that this supply is not enough for the needs of the city, a water famine being occasionally threatened in dry seasons.

Professor Pettenkofer has strenuously opposed all attempts to attribute the improvement to this cause, the procuring of a supply of pure mountain water was followed by such a falling off in typhoid that the disease has now become a rare one there. As extensive improvement in drainage was at the time carried out, the improvement is less clearly due to the change in water-supply than in the case of Vienna.

With the constant increase in population the problem of obtaining water for large cities like London, Berlin, Paris, and New York, becomes more difficult. The question becomes practically narrowed down to carrying water from immense distances, or utilizing the ground-water obtained by means of artesian wells. The former plan is most favored by many English scientists, who are seriously considering the relative feasibility of drawing the London supply from the mountain district of North Wales, at a distance of 180 miles from the metropolis, at a cost of over £11,000,000, or from the lakes of Cumberland and Westmoreland at a cost of over £13,000,000. The main objection urged is not that the engineering difficulties are too great, but rather that in diverting the daily amount of 230,000,000 gallons, estimated as necessary for the needs of London, from another part of the kingdom, they are depriving the cities of the North of England of their natural water-supply. In Germany, on the other hand, the utilization of the ground-water by means of artesian wells seems to find more favor. In Paris no comprehensive scheme for improving the water-supply has yet been matured, but, as in France water is not much employed as a beverage, the question appears to be considered less pressing than would be indicated by the frequency of such diseases as cholera and typhoid.

The present water-supply of New York from the Croton Aqueduct is anything but an ideal one, and the constant presence of from 2,500 to 40,000 bacteria per c. c. in the city supply seems to urgently call for filtration.

Chicago, with the whole of Lake Michigan to draw from, has succeeded in contaminating the water about the city intake so as to render it almost unfit for drinking purposes; but here the question is relatively simple, as by the construction of sewage farms, on the one hand, and the lengthening of the conduit, on the other, a pure supply should be available.

Household Filters.—The question of rendering an impure water drinkable by means of a small domestic filter is one which has not yet received a satisfactory solution. Most of the filters on the market are capable of physically purifying water and making it clear and palatable. Unfortunately, as these filters do not efficiently remove the bacteria, the last state of the water is too often worse than the first. The ordinary carbon, gravel, pumice, sand, glass, and asbestos filters yield a filtrate which usually contains more bacteria than the water from which it was derived, while, if the water originally contained many organisms, they appear in undiminished quantities. The benefit from such filters is purely æsthetic in character, and the filtered water is not one jot improved, from a hygienic standpoint. The failure of filters of this class to remove bacteria from water is due to the following causes: (1) the filtering substance is incapable of retaining bacteria; (2) the receiving chambers form a suitable spot for the subsequent autoinfection of the water; (3) particles of sediment are washed off by the current and appear in the filtrate; (4) the construction of the filters does not permit of their being readily cleansed or sterilized; (5) nitrification does not occur.

As a rule, the ordinary household filter, working in the usual way, shows innumerable bacteria in the filtrate, even when the water appears clean and appetizing. As the first thing we demand of a filter is that it shall remove from the water any germs which may cause disease, it is evident that none can be considered to meet this condition unless the bacteria are almost entirely removed. Recent improvements in construction have done much to remedy this deficiency, and a few filters are now procurable which yield a water free from micro-organisms.

The oldest and best known form is the Pasteur-Chamberland bougie filter, which is made of a hollow chamber of porous porcelain, which is made to fit into a tube attachable to any water-tap. The water percolates through the porcelain, and collects in the central cavity, from whence it drops into the vessel used to collect it. This arrangement is shown in Fig. 672.

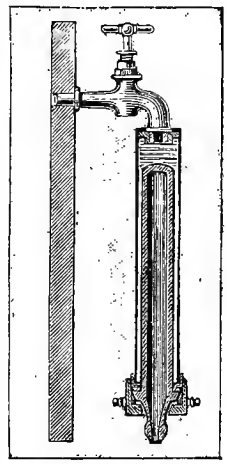

Fig. 672.—The Pasteur-Chamberland Filter.

When a pressure of water is not attainable, the filter may be made to act as a siphon by attaching a rubber tube about 6 feet long to the outlet, and after placing the bougies in a bucket of water, sucking the tube until it becomes filled with water. An arrangement is shown in Fig. 673, by which 3 bougies are simultaneously employed to filter the water from a pail. This simple plan is adapted to meet the requirements of travellers, soldiers on the march, etc.

That a Chamberland filter in proper working order will yield a filtrate absolutely free from bacteria is the universal experience of those who have taken the trouble to test it. There is no doubt whatever that under proper conditions this filter is absolutely germ-proof. There are two drawbacks which prevent it from being an ideal filter: (1) it will only furnish germ-free water for a limited period, usually varying from 3 to 8 days, rarely over 2 weeks, and (2) the amount which can be filtered through it is small. This latter objection is overcome by having "batteries" of 4, 10, 20 or more filter bougies arranged in one pressure chamber, when the water is required for schools, etc. Each bougie will, under moderate pressure, furnish one-half to two gallons per day. In practice, the outer surface of the bougies should be cleansed with a brush at the end of about a week, and should be sterilized by boiling in water, or in a steam sterilizer. One common cause of failure of these filters is the presence of cracks or flaws in the porcelain, through which unfiltered water passes, and such cracks are liable to be produced during sterilization, unless it is carefully done. Under ordinary circumstances, the filtrate at the end of a week has begun to show bacteria. Their presence is usually explainable as due to their having grown through the pores of the filter, but is probably frequently caused by the organisms of dust, etc., lodging at the mouth of the filter and spreading upward into the central reservoir. If

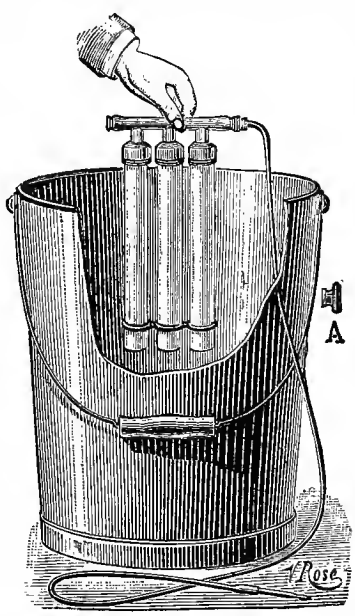

Fig. 673.—Pasteur-Chamberland Filter with simple siphon tube attached.

cleansed and sterilized every week and carefully looked after, the Chamberland filter can be depended upon to furnish water free from bacteria. It has the great advantage of being compact, and having all its parts readily accessible for cleansing and sterilization.

A number of so-called porcelain filters, made on the same pattern, are far inferior to the Pasteur-Chamberland.

It has long been sought to combine the advantages of the Chamberland filter, of furnishing a germ-free water and being readily cleansed and sterilized, with a more abundant supply of the filtrate. Recently several filters have been placed on the market, which profess to attain this, and while none of the rapid filters are absolutely germ-proof, several are capable of accomplishing about what may be expected of sand filtration on a large scale, and give an abundant supply of water from which most of the bacteria have been removed. In some of the best of these, asbestos fibre and infusorial earth are employed as the filtering medium, and an arrangement is made by which the filter can be readily cleansed, and afterward sterilized, by passing steam through it, which is certainly a scientific and thorough method.

Breyer reports very favorable results from the use of an asbestos membrane filter, which yields for several days an absolutely germ-free water under a pressure of between ½ and 1½ atmospheres. The filtering material contains three million pores per square mm. of surface. In practice it is best to renew the filtering material every forty-eight hours. This filter is also found capable of filtering considerable quantities of water, about thirty cubic metres being obtained per square metre of filtering surface, in twenty-four hours. The cost of operating is mainly that of renewing the asbestos.

Nordmeyer and Bitter found that with filters of infusorial earth, a germ-free water was furnished for about a week; the apparatus could readily be sterilized by steam.

It would be out of place here to discuss the individual merits of particular manufactures, but it may be generally stated: (1) That ninety per cent. of all the styles of household filters sold are absolutely unreliable, and do not fulfil their claims, and with the remainder good results can be obtained only by proper management; (2) in all filters, cleansing and sterilizing is necessary at intervals of about once a week; (3) the filter which can be most readily cleansed and completely sterilized is the one to be preferred; (4) all filters which have a receiving chamber, where the filtered water is allowed to stand indefinitely, should be discarded as dangerous.

Sterilization of Water by Heat.—The experiments of Pouchet and Currier have shown that most of the bacteria met with in water are destroyed at temperatures considerably below the boiling point. Currier found that cultures of cholera, typhoid, diphtheria, and pathogenic cocci suspended in water, were killed instantaneously by boiling, or in 15 to 30 minutes at 70° C. Only one species was found which required boiling for an hour to destroy it. Miquel found that in water heated to 45° for 15 minutes, about 75 to 90 per cent. of the bacteria were killed: at 55° about 92 or 93 per cent. were destroyed: at 65° about 95 per cent. Less than 1 per cent. withstood the heat of 100°. This held good of several samples of river water. In other observations the bacteria were almost completely destroyed by ten minutes' heat of 80° C. From this it is evident that in water which has been boiled any pathogenic bacteria present will have been destroyed; hence this treatment of water affords the greatest security in times of epidemic. On the other hand, it has certain disadvantages: boiled water has an insipid, flat taste, and is not refreshing; further, in boiled water which is allowed to stand exposed for some hours an enormous number of bacteria develop, so that it is preferable to boil the water immediately before use. Enthusiasts for hydro-therapeutics appear to find great comfort in drinking hot water, claiming that it is more refreshing than cold. To persons of this way of thinking, the sterilization by boiling would, of course, be highly satisfactory. To ordinary individuals boiled water can only be rendered palatable by aërating, either with air or with carbonic-acid gas, by means of some of the various apparatus designed for the purpose. On shipboard, where water has to be stored in tanks for a long period, it becomes often very foul; and in some cases there is no doubt, very dangerous to health, especially in times of epidemic on board. The greatest safeguard against water contamination at sea is to obtain it by means of condensation. Distilled water obtained by means of condensation apparatus, is now used altogether in the American and German navy, and it has been found that the employment of this system has materially benefited the health of the ships' crews. The condensation apparatus is combined with an aërating process, so that the water is palatable and refreshing.

When large supplies of sterilized water are required for use by a number of people, for instance in case of epidemic in a small town or village, the boiling of the water by individuals is an obvious disadvantage. An apparatus has been devised and constructed by Rouart and Geneste-Hercher for sterilizing the water at a high temperature, namely, 115° to 130° C. The construction of the apparatus, which is simply a special set of coils of pipe, between which hot air is passed, with subsequent cooling and filtering of the water, will be understood from Figure 674

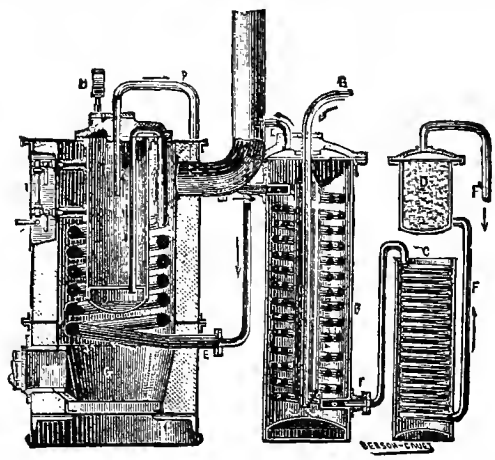

FIG. 674.—Geneste-Hercher Apparatus for Sterilizing Water at 130° C.

With this, for each pound of coal, about ten gallons of water can be sterilized. The municipalities suffering from epidemics are in this way able to furnish temporarily water free from suspicion to large numbers of the inhabitants.

Voller, after investigating water-sterilizing apparatus made by Heaton and Hennike, Burgdorf, Siemens, Strebel, and Jones, found that the Hennike apparatus furnished 180 litres of sterilized water per hour, and the others 25 to 40 litres. The fuel employed was gas, of which 6.11 cbm. were required per 1 cbm. water by the Hennike and 7.50 to 11.60 by the others. In all these apparatus the sterilized water in the process of cooling is made to warm the water about to be sterilized.

Disinfection of Water.—The addition of disinfecting substances to drinking-water has, owing to the poisonous and acrid nature of our most reliable chemical disinfectants, not come into use; however, when proof has been afforded that a well is polluted it is advisable, in addition to cleaning, to thoroughly disinfect it. In the case of tubular wells this is best accomplished, according to Fränkel, by first pumping as dry as possible, then removing the pipe and pump, and placing them for two hours in two per cent. carbolic-acid solution, afterward cleansing with a brush and pouring in several gallons of five per cent. crude carbolic and sulphuric acids. The pumping is to be resumed and continued till no trace of carbolic acid can be detected (tested by the phenol reaction, on addition of perchloride of iron). Fränkel considers the common method of disinfecting by chalk not

adapted for tubular wells. Ordinary wells cannot be completely disinfected by this method.

Peroxide of hydrogen has been added to drinking-water in order to purify it by disinfection. The addition of small quantities of permanganate of potash is also recommended. This acts as a precipitant only, the water being subsequently cleared by agitation with coke.

Mineral Waters.—The examination of natural mineral waters by Malpert-Neuville, Poncet, Roman, Collin, in France; Reinl, in Austria; and Minges, in America, have shown that, taken with proper precautions at the source, these waters are almost free from bacteria. When bottled, however, a rapid increase takes place, so that at the end of twenty-hour hours over 500,000 microbes per c.c. may be met with. Analogous results were obtained by Fränkel, who examined samples of artificially prepared seltzer water. The carbonic acid, with which these waters are saturated, tends to act as a germicide, and where proper cleanliness is used, the bacteria per c.c. in bottled mineral waters should not exceed 250 per c.c.

Carbonic Acid.—The action of carbonic acid on water bacteria has been shown by Leone and Fränkel to be a destructive one. Of the anaërobic bacteria but few exist whose growth is not hindered by the presence of carbonic acid. In spite of the tendency of carbonic acid to destroy bacteria, aërated waters often contain large numbers of bacteria, and in the manufacture of these care should be taken that the apparatus, etc., are kept clean, and that a pure water is employed.

METHODS.—*Procedure to be Adopted with a Sample of Water:*

A. Estimate the number of bacteria per c.c. by gelatine-plate method.

B. Identify as far as possible the different organisms obtained by culture in this method, and the proportion in which they occur.

C. Describe any new species met with.

D. Examine the sediment by the Sedgwick-Rafter method.

The directions given here are intended for those who are familiar with the ordinary processes in bacteriology; information on which is found under the headings "Micro-organisms," Vol. IV., and "Bacteriological Technology," in the present Supplement.

The object of special methods for water analysis is chiefly to guard against certain sources of error. There is no work in which mistakes can more readily be made, and wrong inferences drawn. Methods which, while not absolutely accurate, afford little chance for making a serious mistake, are to be preferred to more delicate methods capable of misapplication. Rapid and simple methods enable the observer to make a larger number of individual observations than more complicated and precise ones, and the ultimate precision obtained through a large number of simple observations is usually more correct and reliable than that obtained by a smaller number of complicated ones.

The greatest safeguard against error lies in the duplication of all work, and the comparison of the results so obtained. Thus, at least two observations should always be made, and each of these should be done in duplicate, and, to check them, the whole process repeated. If corresponding results obtain throughout, the observation is reliable. The importance of using expeditious methods is therefore clear.

As the biological characters of a water are different at various seasons, various points, various depths, etc., it is necessary that, where possible, the observations should deal with the water in all its different phases, in order that the extent of its variations may be learned. The biological work is, for convenience, divided into bacteriological examination, and examination of the other microscopical organisms, such as algæ, infusoria, organized and unorganized *débris*.

Loss of time between the collection and examination of samples is fatal to accurate results. This is especially true of the bacteria, but also of the other organisms. The interval between the collection and plating for bacteria should be, if possible, only a few minutes, and certainly less than an hour. For the other organisms the examination should be completed within one or two days of the time of collection.

The Collection of Samples is a matter which, where possible, should be done by the analyst himself and not deputed to others, except where the conditions of the water are such as make it a mere matter of routine. The points to be attended to are: 1, To get samples characteristic of the whole body of the water, for which purpose it is always best to obtain as many different specimens as possible; 2, to take them under such precautions as render the occurrence of contamination from the hands, dust, etc., out of the question. For work other than bacteriological, a glass-stoppered bottle containing one or two litres is on the whole the most convenient. Especial care must be taken that it is so thoroughly cleansed that, when rinsed out with distilled water, no organisms are found in the washings. The stopper is only to be removed at the moment when the sample is being taken. In the examinations carried out by Boards of Health the bacteriological examination is often made from water taken in this way, and transported to the laboratory for analysis. In this case the bottles require to be sterilized by heat before use. Although this, with proper precautions, gives fairly accurate results, and is better than omitting the bacteriological examination altogether, it is far preferable that separate samples be collected for bacteriological work in smaller bottles, that a large number of these be taken, and that the cultures be made at the time and place of collection, if this is more than a few minutes' journey from the laboratory.

For bacteriological samples the use of test-tubes, or Erlenmeyer's flasks, is usually recommended, the directions given being that after plugging with cotton wool and sterilization these should be covered by a rubber cap, which is only to be taken off at the time of collection of the sample. The contact of the rubber cap and the wadding with the fingers is to be avoided, and the bottle is to be immersed before removal of the stopper, and the sample taken some distance below the surface, holding the bottle or tube in such a position that it is not exposed to washings from the hands and arms, or other sources of contamination. It is well to discard the original plug of the bottle, and replace it by a fresh one. A good plan is to use sealed tubes, or Sternberg's bulbs drawn out to a fine point, which can be broken under water, and can be sealed again if transport is necessary. For making cultures the ends are broken off. This, as far as freedom from contamination is concerned, leaves little to be desired, but the trouble in making and sealing a bulb for each sample is considerable and requires to be done in the laboratory.

An ingenious method, adopted by Miquel, makes it possible for samples to be taken in this way at any required depth below the surface, by the apparatus shown in Fig. 675, where the pointed end of the sealed flask is curved and broken at *A*, by means of a string, at the required depth. This has been further improved by H. L. Russell, who inserts a sterilized rubber stopper into the test-tube, through which is passed a piece of bent glass tube, sealed at the end and broken by the descent of a lead weight running along a wire, as shown in Fig. 676.

The writer has found it convenient to employ, for a collection of samples, dropping bottles of about 50 c.c. capacity, which are fitted with pipettes that serve as ground-glass stoppers. For collecting purposes these are placed in a special frame, as shown in Fig. 677, and the stopper raised at the required depth by pulling on the string or wire attached to a movable cross-bar; the apparatus being sunk by the weight of the box forming the base of the frame which is filled with shot. This apparatus is modified from one introduced in 1885 by Wynter-Blyth and invented by Mr. A. F. Strafford ("Proc. Roy. Soc., Edin., 1885–1886"). The modifications consist merely in a more convenient method of holding the bottle and stopper. For working at depths of less than fifty feet this apparatus leaves little to be desired; at greater depths it is difficult to manipulate the lines at-

tached to the cross-bar and sinking-frame. The bottles, when opened under water, fill in the course of ten to fifteen seconds, and can be withdrawn and replaced by others. Ten samples of water can be taken, at a depth of ten to twenty feet, in this manner, in less than a quarter of an hour. The writer at first used to seal the ends of the pipette stoppers, but latterly he has employed some which are graduated, the rubber cap being placed in position after sterilizing, and in this way the necessity of a separate set of sterilized pipettes for making the cultures is done away with. Where it is not necessary to take the samples at any considerable depth, a simple lead sinker may be employed, attached by a wire or string to the neck of the bottle, which is then immersed by using a fishing-rod and line, a method very convenient for obtaining samples from the banks of streams, from bridges, from steamboats in motion, etc.

An apparent objection to this apparatus is that the attachments to the collecting-bottle for opening and closing it being external, are liable to contamination, though the uniformity of the counts obtained shows that it does not actually occur. Dr. George H. Nuttall suggested a most ingenious idea by which the springs for closing the bottles were to be placed inside it. A method also suggested was filling a bottle with sterilized mercury and allowing it to escape at the required depth. (Bertin-Sins.)

Transport.—The bottles used for collecting samples should be secured from contamination of all sorts previous to use, and when the water samples have to be kept for more than half an hour previous to making cultures, they should be cooled to about 0° C. The writer found it convenient to place the bottles in a tin box, the lid of which is furnished with a handle and lock. The box can be surrounded by ice in an external jacket, or the lid converted into a tray in which ice is placed, a tube carrying off the water which collects. In this way security from contamination and cooling of the water are secured. Refrigerating boxes for the transport of samples have been devised by Pfuhl, G. Roux, and others, in which the samples enclosed in a water-tight box are surrounded by a non-conducting substance, usually sawdust, and packed in ice. According to Miquel, the number of bacteria developing from samples of water kept even at 0° C. for several hours, is sometimes considerable, and on this account the transport of samples for long distances is undesirable.

G. Frank has recommended the shipment of a small box containing the materials necessary for making cultures at the spot of collection, together with printed cards of instruction by which the cultures can be made by persons without technical skill, such as sanitary inspectors, or the laity generally. This, however, must be regarded as a poor substitute for skilled manipulation, and the choice between shipping samples of water or allowing the cultures to be made by unskilled hands, is but a choice of evils.

Quantitative Bacteriological Analysis.—It will be understood that the cultures are to be made, where practicable, on the spot where the samples are collected, with the least possible loss of time. The bottles containing the samples are first shaken thoroughly to insure the uniform distribution of the organisms throughout, and to break up any bacteria masses or clumps that may be present. By always giving one hundred violent shakes to every sample of water, very uniform results are obtained. Instead of using plates, roll tubes, or Petri dishes, the cultures may be made in small, flat-sided glass vials, such as can be obtained from any apothecary. The "Blake" vials, holding two to three ounces, are most convenient. These, when cleaned, plugged, and charged with 5 to 10 c.c. of flesh-peptone gelatine, should be sterilized on two or three successive days, just as with gelatine tubes. Before use their gelatine should be melted by placing them in a pan of tepid water at a temperature not above 40° C. Labels can be placed on the necks of the bottles, and it is convenient to employ for this purpose gummed paper cut into long strips, which are nearly torn across after having been written upon.

With a graduated pipette, ten to twenty of which should be kept ready for use in a small tin box (where the graduated pipettes do not form part of the stopper), a quantity of water, say 1 c.c., should be measured out and dropped into one of the bottles containing gelatine; ½ c.c. is put into a second bottle, and a smaller quantity,

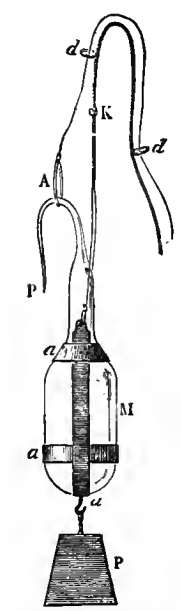

Fig. 675.—Apparatus for Collecting Samples at Desired Depths (Miquel).

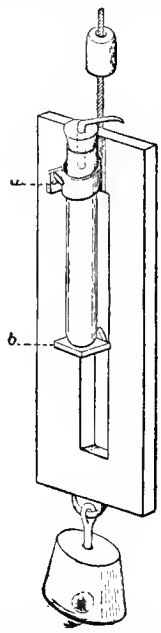

Fig. 676.—Apparatus for Collecting Water Samples at Great Depths (Russell).

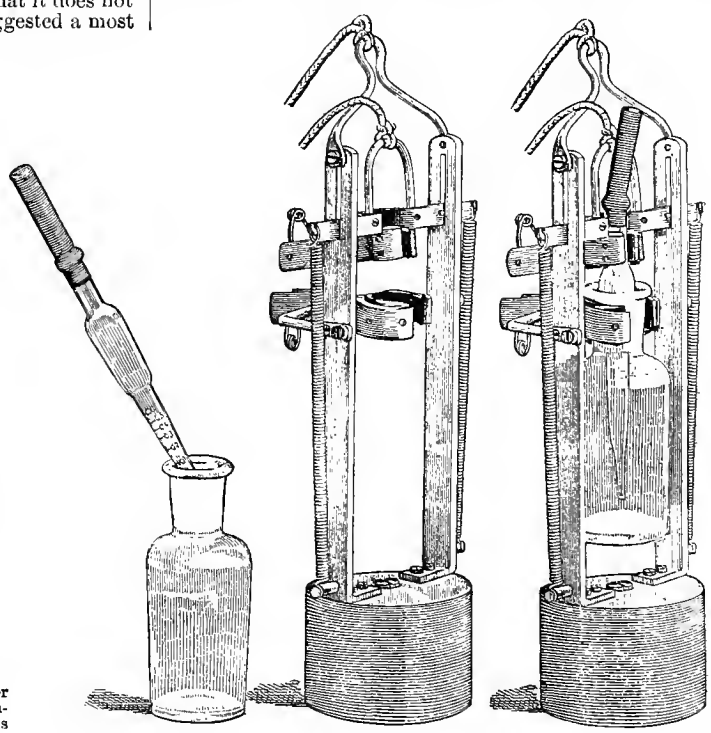

Fig. 677.—Apparatus for Collecting Samples of Water below the Surface (Johnston).

either $\frac{1}{10}$ or $\frac{1}{20}$, into a third bottle. The bottles are then gently shaken, so as to secure uniform distribution of the germs, and then to be laid on their side till the gelatine stiffens. The hardening of the gelatine is materially hastened by laying the bottles upon a flat lump of ice. Before making the cultures the cotton-wool stoppers should be loosened by turning them half round, so as to make sure that no gelatine has stuck to the wool. It is convenient to use pipettes holding 1 c.c., graduated to $\frac{1}{10}$ c.c., and these should preferably discharge drops of $\frac{1}{20}$ of 1 c.c., so that one drop equals $\frac{1}{20}$ c.c., and two drops equal $\frac{1}{10}$ c.c.

By employing various fractions of a cubic centimetre in the same sample a valuable control is secured, as the accuracy of an observation will depend upon the extent to which the numbers of colonies correspond to the amount of water introduced. Thus, in a water containing 100 bacteria per c.c. (that is to say, yielding 100 colonies by the gelatine method per c.c.), a whole cubic centimetre should yield 100 colonies; a half cubic centimetre, 50 colonies; $\frac{1}{10}$ cubic centimetre (2 drops), 10 colonies, and the $\frac{1}{20}$ cubic centimetre (1 drop), 5 colonies. If this proportion is materially altered—for instance, if the smaller fractions give higher counts than the larger ones—we are warned of a mistake somewhere. The fractioning method has the further advantage that, where the water contains more bacteria than was anticipated, and the colonies are so close set, or the liquefaction so rapid, that the culture made with an entire cubic centimetre cannot be accurately counted, the smaller fractions will still give countable plates. For accurate work care should be taken that the number of colonies developing on any one plate does not materially exceed one hundred.

The smaller fractions usually give counts proportionally higher than the larger ones; for instance, where 100 colonies grow from 1 c.c., about 60 may appear from $\frac{1}{2}$ c.c., and 12 or 13 from $\frac{1}{10}$ c.c. This is owing to the fact that, in the thickly sown plates, crowding of the organisms may cause a single colony to be formed in some cases from the fusion of two or more distinct centres of growth. In densely set plates smaller colonies can often be seen lying within the larger ones. For this reason the number shown by the greater dilutions is more accurate, and the multiple of this number representing cubic centimetres preferable.

To exclude the personal or subjective factor as much as possible, the average of the different plates should be taken and used for record, but at the same time it is most important that the maximum and minimum should also be noted, as *the difference between these*, when recorded, furnishes a permanent indication of the accuracy of the work. The statement of average numbers only is therefore to be deprecated.

When the bacteria in the water are represented by many thousands, as is the case with impure waters, the water should first be diluted before making the cultures. This is done by adding 1 c.c. of the water to be examined to 100 c.c. of sterilized tap-water, mixing thoroughly by shaking, and taking of this mixture 1 c.c. and its fractions for making the cultures. The results must, of course, be multiplied by one hundred. Where the numbers run into hundreds of thousands or millions per c.c., it is necessary to make a second dilution by taking 1 c.c. of the diluted water and adding it to 100 c.c. of sterilized water, multiplying the number of colonies by ten thousand. In addition to this, as a control, the number of colonies may be also estimated by dividing 1 c.c. or less of either the dilutions or the original water among a series of cultures. As a general rule, it may be stated that the system of dilution is more reliable than that of trying to take very minute fractions with a fine pipette.

Gabritchewski recommends, in the case of highly polluted water, the employment of capillary pipettes of extremely fine calibre for making the dilutions, so that direct measurements can be made of $\frac{1}{100}$, or even $\frac{1}{1000}$, of a cubic centimetre! The fluid is driven out by means of a finely graduated screw compressing a rubber tube, as shown in Fig. 678.

This plan is possibly preferable to dilution, when much field work is to be done, with water polluted to an extreme degree. As these capillary pipettes save space, by doing away with the necessity of providing a supply of sterilized water, a larger number of examinations could be made and time saved. On the other hand, it is not possible actually to measure out such extremely minute quantities of water with certainty, owing to the disturbance due to capillary attraction, which tends to make the drops so large that quantities representing .01 c.c. can only be reckoned upon when the water is dropping at that rate from a burette for some minutes together. Dilution with sterilized water is more accurate and reliable than that of capillary measurement, and it may also be mentioned in this connection that the polluted waters do not tend to undergo the rapid changes on keeping which characterize pure waters (Miquel), and therefore slight delay before plating is not so objectionable as in the case of the latter.

A source of error, not generally known, appears to lie in the fact that the number of colonies developing from a given quantity taken into the dry pipette is less than when the process is repeated a second time. This I consider due to the fact that bacteria tend to adhere to the sides of the pipette. My observations have become more uniform since I adopted the practice of rinsing out the sterilized pipette with the water, and refilling it before making the examination.

The cultures are to be kept in a dark place, at a temperature of, as nearly as possible, 20° to 22° C. The influence of temperature upon the uniformity of results is very great, and in the winter a warm room should be selected, or an incubator kept by means of a small flame at the desired temperature. In the summer, if the room be too hot, the same result may be obtained by allowing a stream of water at a temperature of 20° C. to flow through the incubator. Kinyoun and others, working in the Southern States, have adopted a simple plan of placing the cultures in a tin box covered with linen cloth, which is kept constantly moist, and the evaporation from which secures the desired temperature. For field work, or on journeys, a small portable refrigerator may be employed, consisting of a double-walled tin box with a tray of ice, from which the water can escape by means of a tap.

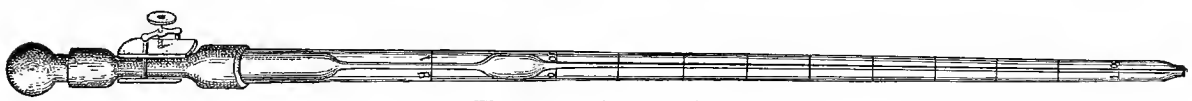

Fig. 678.—Capillary Pipette (Gabritchewski).

The colonies begin to appear at the end of about forty-eight hours, and their number should then be noted. In doing this the use of a powerful hand lens is necessary to distinguish the smaller colonies; the counting is facilitated by ruling parallel lines with ink, or by means of a writing diamond, on the exterior of the bottle, two longitudinal ones usually sufficing. The culture bottles should be placed upon a black background to bring the colonies into sharper relief. The side to which the gelatine has adhered should be placed uppermost.

To prevent the possibility of mistakes in enumeration, and to relieve the mind of the strain of constant attention to a monotonous series of numbers (a constant source of worry and irritation), the use of an automatic tally, such as is used by drovers for counting the animals in their flocks, or by officials for checking the number of passengers on ships, is highly to be recommended, as the counting then becomes automatic, and the mind is left free to attend to other details, such as the appearance of the col-

onies. Further, by employing a tally, the interruption by one's friends no longer becomes a thing to be dreaded.

When the number of colonies in a plate is very great a definite portion of the surface only may be counted, and taken as an average of the whole.

The colonies should be counted upon successive days, and any increase noted. When no further increase occurs, say at the fourth or fifth day, the number may be adopted as correct. This maximum number is usually obtained at the end of three to five days, about fifty per cent. appearing at the end of forty-eight hours. It not infrequently happens in the later days of growth that the number apparently decreases slightly instead of increasing, a circumstance which is explainable by the tendency to confluence of colonies, and which indicates that the maximum development has been reached.

While estimating the total number of colonies, the proportion of the more striking and important species should also be noticed. To do this without loss of time properly ruled pages are essential, and this is readily obtained by the use of a rubber stamp, giving parallel lines. I have come to employ altogether small scribbling-books of convenient size, about four by five inches, and to number each sample serially. The employment of serial numbers greatly facilitates labelling. Duplicates of the same sample can be indicated by employing letters, thus: 360, 360 A, 360 B, indicate three duplicate samples from the location from which sample 360 was obtained. The fractions are indicated on the labels and in the notes by placing the dividend beneath the number of the samples; $\frac{360}{2}$, $\frac{360}{10}$, and $\frac{360\ A}{2}$, $\frac{360\ B}{10}$, etc., represent the fractions $\frac{1}{2}$ c.c. and $\frac{1}{10}$ c.c. The numbers of the examinations contained in each book can be shown on the outer page, so that the whole series of a prolonged analysis is always ready for reference and indexes itself, so that any of the examinations can at once be referred to.

Instead of making cultures in the glass vials here described, which satisfactorily replace the more expensive "Petruschky" flasks—and which I find to have been recommended by Schill and others—Petri dishes or Esmarch tubes can be made use of. Esmarch tubes have the disadvantage of requiring time and attention in rolling, just when time is most valuable and can least be afforded. The liquefaction of the colonies in them is a disaster, and the counting is somewhat difficult.

Petri dishes, though more convenient for counting, and requiring less time, do not offer perfect security against admission of germs from the air, where repeated countings are made on successive days. They also require double the amount of apparatus, as the gelatine tubes are also necessary. Further, a variable number of organisms remain in the tube, and do not appear in the plates. The necessity of labelling separately both the tubes and dishes, with the possibility of pouring the wrong tube into a plate, by mistake, is also an objection. The use of the original plate method of Koch with the moist culture chamber jar, offers too great possibility of contamination from the air. In such cultures the presence of moulds is very frequent, and Koch himself always allowed six foreign colonies as a minimum for each plate.

Arloing has contrived a complicated mechanical apparatus by which the growth from drops of water, being delivered exactly in the centre of the square of gelatine, can be distinguished from those due to air contamination, where the colonies are equally likely to fall on other parts of the square. As far as I know, the method has never been adopted by any other person, and presents no especial advantages.

The only point in which the use of common glass vials is inferior to other methods is that, in a blurring from the thickness of the glass, microscopical characters of the colony are less delicately shown than in the thin Petruschky flasks. This disadvantage is more than compensated, in the case of field work, by the readiness with which glass vials can be packed, and by the ease with which they may be set up on end before use, and laid down afterward, or packed one above the other. Moreover, the blurring of the colonies can be remedied by removing the Abbé condenser before examining them, and using a simple mirror illumination, or by the use of a correcting lens for the objective. I have become so pleased with glass vials that I now employ them almost exclusively for gelatine-plate cultures in pathological and bacteriological work.

For counting the colonies several devices have been suggested. The original plan of Wolfhügel called for the use of a square plate of glass, upon which cross lines were drawn, each enclosing an area of one centimetre square. The plate is placed beneath this, and a dark background of slate is used as a relief. A lens mounted on a tripod is used to magnify the colonies. Running diagonally from opposite corners of the plate are two lines of squares, subdivided by finer cross lines into nine divisions, for convenience when the colonies are densely set. It was usual to count only six squares and average the result. This well-known apparatus is not much used at present, as the use of glass plates has been abandoned in most laboratories.

Personally I found it more convenient, in working with Petri dishes, to use a simple school slate, upon which cross lines were scratched, so as to form squares of 1 c.c. or subdivisions of these. A complicated and somewhat

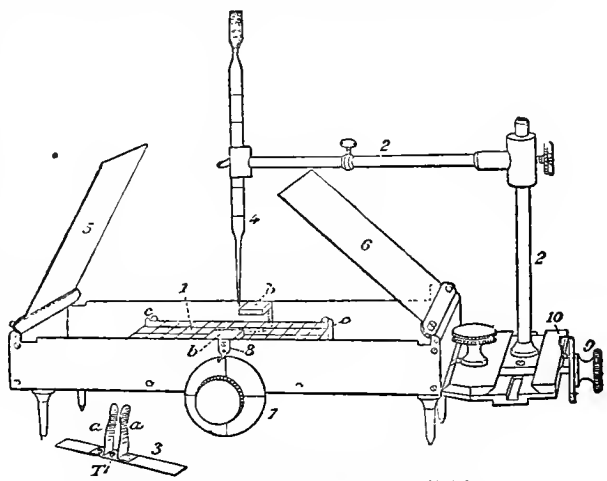

Fig. 679.—Apparatus for Plating Water Cultures (Arloing).

expensive apparatus for Petri dishes has been devised by Heyroth. The illumination by means of a mirror I have not found satisfactory. Petri employed a somewhat similar apparatus, when he first introduced the use of culture dishes. For studying the finer details of cultures in plates the Petri dish is highly satisfactory.

G. Roux recommends photographing the colonies, by allowing the plate or flask to stand over a sensitized albumin paper, which is subsequently developed and fixed, and gives an excellent reproduction both of the number and appearance of the colonies. This method was previously recommended by others. It has the advantage of effecting considerable saving of time, and preserving the proof of the exact nature of the culture.

Certain other methods for the quantitative analysis deserve mention. Some French bacteriologists have shown a tendency to depreciate the gelatine-plate method and to employ the fluid cultures, especially peptone bouillon. Quantitative results by bouillon cultures can be obtained by means of dilutions. Miquel recommends the addition of extremely small drops of water, $\frac{1}{100}$ to $\frac{1}{1000}$ c.c., to small quantities of bouillon, contained in Pasteur's flasks. To avoid the contamination of air, and facilitate manipulation, a burette is used. A portable field outfit, devised by Miquel, is shown in Fig. 680, and contains, in addition to the bouillon flasks, fifteen flasks for making gelatine plates (*p*).

Single drops of the water, pure or diluted, 1 to 100, 1 to 1,000, 1 to 10,000, 1 to 100,000, with bouillon, are

sown in each flask, and the series of flasks is then placed in an incubator at 30° to 35° C. for twenty-four hours, and the number of flasks showing turbidity is noted. As Miquel has found that one-fourth of the bacteria in a water, under these conditions, are capable of producing turbidity at the end of twenty-four hours, the proportion of flasks showing turbidity multiplied by four, and again by the dilutions which the proportion of one drop delivered from the pipette bears to 1 c.c., will give the number of bacteria per c.c.

For example, take one drop of a water representing $\frac{1}{100}$ of a c.c., dilute this with bouillon into fractions of 1 to 100, 1 to 1,000, and 1 to 10,000 of ten flasks, and seed ten flasks from each of these dilutions; if the flasks seeded with the 1 to 100 dilution all become tur-

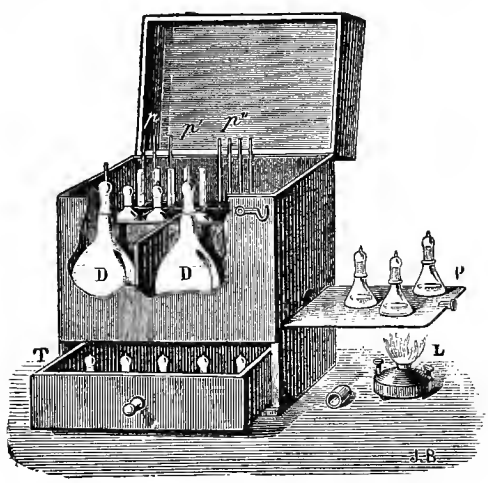

FIG. 680.—Miquel's Portable Outfit for Field Work, with Flasks and Graduated Pipettes. The conical bottles contain nutrient gelatine.

bid in twenty-four hours, and of those seeded with 1 to 1,000 three become turbid, while all of the 1 to 10,000 remain clear, it is evident that as $\frac{3}{10}$ represents one-fourth of the number presumably present . ·. $\frac{3}{10} \times 1{,}000 \times 100 \times 4 = 120{,}000$ bacteria is the number per c.c. The great source of error lies in the enormous degree of dilution, by which an error is multiplied over one thousandfold. Thus two bacteria getting by accident into one of the drops in the 1 to 1,000 solution, in the case cited, would have lowered the result to 80,000 per c.c.

Miquel only employs this as a preliminary (*approximative*) method, keeping the water at a temperature of 0° C. till the following day, when a further large series of flasks are seeded to determine more accurately the number present. A certain degree of patriotic enthusiasm for things French would appear indispensable to rate the practical value of this highly ingenious and scientific above the gelatine-plate method.

Without underestimating the value of M. Miquel's discovery that water contains far more bacteria than are revealed by gelatine plates, it must be remembered that the value of enumeration lies in comparative rather than absolute standards of measurement.

Miquel insists that his method is a very simple one, but except in France it has never come into general use. It certainly has the advantage of recognizing a large number of bacteria which grow poorly or not at all on gelatine at room temperature.

Another method suggested by Miquel consists in the employment of papers saturated with nutritive media, which are moistened with the water in question, and after remaining in a moist chamber for some time are treated with a solution of indigo and sulphuric acid, by which means the number of colonies are recognized by the appearance of the bluish spots. This has never come into general use, and even Miquel, while deprecating the employment of the gelatine method, appears nevertheless to use it himself.

QUALITATIVE BACTERIOLOGICAL ANALYSIS.—Until recently but little systematic study has been attempted of the various species isolated from water. The number of the different forms met with, and the difficulty of distinguishing and identifying them, or of determining from published descriptions whether the forms described by one author correspond with those of another or not, has retarded progress in this direction.

The determination of the nature and properties of the germs found in water has been called "qualitative" analysis, and is distinguished from quantitative, where the number present forms the chief consideration. From a hygienic stand-point great benefit should be expected, *a priori*, from qualitative work in bacteriological water analysis. In particular the recognition of pathogenic bacteria would appear to be of great importance, since it is the presence of disease-producing germs which creates the dangerous element of water. On the other hand, the actual results of work in this direction have been far from satisfactory, partly because, owing to the number of other forms, the recognition of the few pathogenic germs is extremely difficult, as they are sparsely distributed, and minute quantities of water only can be examined by the ordinary methods employed.

A further difficulty is caused by the great resemblance borne by a number of common water bacteria to pathogenic ones, notably the typhoid bacillus, of which almost the exact counterpart can be found in most samples of drinking-water by careful search.

Considerable improvement has lately been effected in the direction of the more ready and certain isolation of pathogenic bacteria in water, consisting of: 1. Culture methods, by which the growth of the pathogenic microbes is favored, while the growth of other bacteria is prevented. 2. Methods enabling larger volumes of water to be employed. 3. More exact study of the characteristics of water bacteria, and comparison with pathogenic forms in parallel cultures.

Our classification of bacteria is still far from perfect. The great advance, due to the introduction of the gelatine-plate method, and the readiness with which a number of species can be recognized by it, have led to its too exclusive use. A further evil attending this one-sided work has been a separation of groups which are, on the whole, closely connected, simply on account of their liquefying gelatine or not. An attempt to place the classification on a broader basis has been made by Miquel, whose scheme is given in the following table:

MIQUEL'S SYSTEM OF CLASSIFICATION (MODIFIED).

A. Cocci.
B. Bacilli.
C. Spirilla.
D. Other forms.

A. Cocci. 1° Aërobic and Facultative Anaërobic.
2° Anaërobic.

A. 1° Aërobic. α Develop at 20° C.
β Develop at 20° to 40° C.
γ Develop above 40° C.

A. 1° α. I. Pathogenic.
II. Zymogenic (specific ferments).
III. Chromogenic.
IV. Saprogenic.

A. 1° α I. a. Liquefy gelatine.
b. Do not liquefy gelatine.
c. Do not grow in gelatine.

It will be noticed that qualitative and quantitative analyses have been treated here somewhat as if no intimate connection existed between them. The reason for this is simply that, owing to the immense amount of time required for biological water analysis, and the number of pressing duties which simultaneously engage the attention of those working at it, it is all but impossible to carry them on simultaneously without assistance. It looks, indeed, as if the thorough analysis of a drop of water would soon demand the attention of a number of indi-

viduals, just as it formerly was said to require ten men to make a pin. To combine quantitative and qualitative biological analyses of water, when done thoroughly, requires so much time that it is seldom called for, several months of uninterrupted labor being necessary for the complete analysis of a single sample, to the exclusion of all other work. An outline of such an analysis, given by Miquel, is appended here.

It is to be hoped that in the future, with continual improvements in our methods, some such satisfactory results will be ultimately arrived at by more speedy means, and that analyses of this sort will become the rule instead of the exception.

COMBINED QUANTITATIVE AND QUALITATIVE ANALYSES.

Bacteriological Analysis of Seine Water, August, 1890 (Miquel).

Quantitative analysis: bacteria per c.c.		397,500
Growing on gelatine	312,400	
Growing only other media	85,100	
	397,500	
Aërobic bacteria	334,000	
Anaërobic bacteria	63,500	
	397,500	
Growing at 20° to 40°	368,000	
Growing at 40° to 50°	26,500	
Growing at 55° to 70°	3,000	
	397,500	
Qualitative Analysis:		
Pathogenic species per c.c.	16,900	
Zymogenic species per c.c.	95,000	
Chromogenic species per c.c.	125,000	
Indifferent species per c.c.	110,000	
Undetermined species per c.c.	50,600	
	397,500	
Of the chromogenic species		125,000
Yellow species	68,000	
Orange species	2,500	
Green species	2,200	
Red species	35,600	
Violet species	500	
Blue species	1,500	
Intermediate colors	14,700	
	125,000	
Of the yellow species sub. group		68,000
Citron colonies	Bacterium xanthidenm.	
	M. citreus conglomeratus.	
Greenish colonies	M. chlorinus.	
	Sarcina ventriculi.	
Brown colonies	Spirillum tyrogenum.	
Yellow colonies	Sarcina lutea.	
	B. cavicida.	
	B. hyacinthi.	

The writer finds it convenient, in connection with the quantitative analysis, to note the proportions in which some of the commonest and most easily recognized species are present, the results being tabulated, as shown in the accompanying record of an analysis of Ottawa River water:

Ottawa River at L'Original, May 1, 1891.	1	1/2	1/10	A	A/2	A/10	B	B/2	B/10	Per cent.
May 3	92	67	8	104	51	11	86	45	10	127.5 per c.c.
May 4	120	65	13	130	63	11	90	48	10	
May 5	122	67	13	140	65	12	liq.	....	12	
May 10	....	....	13	....	....	14	....	....	12	
B. fluorescens liquefaciens	24	10	....	....	....	....	....	....	....	23
B. arborescens	14	....	....	....	....	....	....	....	....	12.5
B. janthinus	2	....	....	....	....	....	....	....	....	2
B. nubilis	6	....	....	....	....	....	....	....	....	3
B. megatherius	1	....	....	....	....	....	....	....	....	1
B. aquatilis	3	....	....	....	....	....	....	....	....	3

QUALITATIVE METHODS.—*Microscopic Examination.*—The examination of a drop of water under the microscope, by simply placing it on a slide and covering it with a cover-slip, was formerly considered to be a highly scientific operation and one yielding valuable results. In discussing this primitive method, Dr. Cahen, of Nancy, goes so far as to say that it constitutes the best means of performing a bacteriological analysis of water; a statement which, being made in 1886, was certainly considerably behind the times.

The bacteria can be advantageously studied by, after evaporating, fixing a drop of water on a cover-glass. Most works giving directions for bacteriological analysis of water recommend that, in each case, several drops of water should be placed upon clean covered glasses and allowed to evaporate beneath bell-jars or glass covers to protect them from the dust. They are then to be fixed by passing through a flame in the usual manner, and stained by a watery solution of an aniline dye, either fuchsin, methylene blue, or gentian violet being selected. The object of this method is, of course, to insure the detection of the forms which do grow poorly or not at all in the culture media. It has been generally ignored by bacteriologists as being unsatisfactory. The better way of attaining the same results is to filter some of the water (several cubic centimetres, 50 to 100 generally suffice) through clean sterilized sand, and to obtain with a sterilized platinum needle or loop a little of the sediment retained, smear that upon a cover-glass, and stain. Few bacteriologists carry this out, although the advantages are obvious.

The staining fluids employed for examining bacteria of water are the ordinary aniline stains as used in other departments of bacteriology, and no special details need be given here. The best methods of staining the nitrifying organisms consist in the employment of extremely dilute solutions of gentian violet, followed by equally dilute solutions of malachite green. The employment of Gram's method is, of course, advantageous for ordinary purposes with the use of a counter-stain, such as fuchsin or saffranin for the organisms which are decolorized by it.

The microscopic study of water bacteria consists chiefly in the examination of the colonies in plate cultures. For determining the different species present this is one of the most valuable means at our disposal. The appearance of colonies under a low power (should be one inch or half-inch objective [AA or BB Zeiss]) is very important. Details of the appearance at different stages of growth should be carefully noted; the size, shape, color, structure, the appearance of the border of the colonies, the presence of motion among their granules, the formation of internal markings, the appearance of the edge in the surrounding gelatine, etc., are the points which afford the chief means of distinction.

In addition to this, dried cover-slip preparations should be made of the organisms of different colonies by fixing in the usual way and staining. The examination can be made, either in water, or after drying and mounting in balsam. The use of an oil immersion-lens is necessary.

For recording observations graphically, camera lucida drawings can be employed, or preferably, when practicable, micro-photographs. Though the latter alone are recognized as possessing scientific accuracy, and being free from subjective errors of observation, a great drawback to micro-photography is to be found in the fact that faithful prints of the negatives are extremely difficult to obtain. When copies have to be multiplied the various photo-gravure and lithographic processes leave much to be desired, and it must be confessed that the great majority of the photographs hitherto published resemble one another to a painful degree, and are rather unsatisfactory. On the whole, the graphic representation of colonies is in a highly unsatisfactory state.

CULTURE MEDIA.—For the culture of water bacteria the ordinary nutritive media, both liquid and solid, suffice. Of these a large variety have been suggested by different authors, and are constantly being added to. For marine species, salt water is to be employed, instead of fresh, in making up the solutions.

Nutritive Gelatine.—Of the various formulæ suggested, that of Miquel is the only one presenting a striking deviation from the ordinary formula. He uses peptone, 20 grammes; table salt, 5 grammes; wood ash, 0.1 gramme; water, 1,000 c.c.; to this bouillon 100 grammes of gelatine

must be added. The reaction should be faintly alkaline, and as the wood-ash and peptones are usually decidedly alkaline in reaction, the addition of a few drops of a weak solution of tartaric acid is necessary. I have found some difficulty in obtaining this medium free from turbidity, and prefer to use a nutritive gelatine made by adding ten per cent. of gelatine to the classical Loeffler bouillon, obtained by boiling an infusion made from one pound of can beef to a litre of water, with ten grammes of peptone and five grammes of salt added per litre and carefully neutralizing. It is preferable that, instead of trying to vary the nutritive media, a well-known medium should be employed, as by this means the results of different observers are more likely to correspond. Slight variations in the composition of a medium are productive of considerable modifications in the appearance of the colonies, so that the same organisms may be described as different species. For this reason it is well to refrain from using the convenient and economical method of making bouillon from meat extracts, the addition of sugar, etc. It is convenient to have on hand two kinds of gelatine, one faintly alkaline and the other slightly acid, growth on acid gelatine being a valuable means of distinguishing certain species.

In some cases a modification of the gelatine may be necessary in order to study forms which do not grow in the ordinary medium; thus Pohl found, in the examination of swamp waters, that the addition of carbonate of ammonia to the gelatine, in the proportion of 0.5 to 1 per cent., favored the development of certain species, especially putrefactive forms, and certain spirilla. The addition must be made after the gelatine has been sterilized, and subsequent boiling must be avoided, as this interferes with the coagulation of the medium.

Drossbach recommends the employment of vegetable albumin, starch emulsions, etc., for obtaining pure cultures of certain spirilla, which do not grow in the ordinary gelatine. The infusions are first diluted in sterilized water, and drops of the diluted material spread upon the nutritive substance, which is then partially dried beneath a vacuum pump: the growth remains entirely confined to the surface, and contamination from deeper colonies is not to be feared. This modification of the dilution method appears likely to furnish material aid in certain cases.

Agar.—The agar medium, employed in the cultivation of water bacteria, is simply that made by adding one to two per cent. to the Loeffler bouillon. It is better to avoid the addition of glycerine or sugar, as this interferes somewhat with the normal development of color in the chromogenic forms.

Potato.—The most convenient form for potato cultures is that recommended by Bolton and Globig, where small cylindrical blocks are placed in sterilized test-tubes. Attention should be given to the reaction of the potato, which should be faintly acid, as the production of color and the form and appearance of the colony are modified considerably when the reaction is alkaline or neutral. New potatoes have usually a neutral reaction, older ones an acid one. To insure a clean white surface in the potato blocks, they should be soaked for several hours in a stream of running water before sterilizing, in order to remove a juice which subsequently turns brown and discolors them.

Serum.—Serum from the blood of the ox is the most commonly used form. Pleuritic or hydrocele effusions also yield a satisfactory medium. By preparing the serum tubes in the way recommended by Hueppe, of first coagulating them at a temperature of 67° to 75° C., and then raising the temperature to 95° C. for half an hour, repeating the sterilization at 95° on two successive days, this medium can be prepared with less trouble than almost any other. As a rule, water bacteria do not grow well upon serum.

Bouillon.—The ordinary slightly alkaline beef-peptone bouillon of Loeffler is now generally recognized as the standard. For the sake of the uniformity, modifications of this solution are, therefore, not to be recommended. For testing the chemical changes produced by bacteria the employment of Dunham's peptone solution is preferable to the use of Loeffler's bouillon, as it is quite colorless, and the detection of delicate color reactions is not interfered with by the presence of yellow pigment in the original solution. It is prepared by dissolving 1 per cent. of peptones (Witte's peptone is the most uniformly colorless) with 0.5 per cent. of common salt, and should be neutral.

To recognize acid and alkali formation add 0.5 per cent. of coralline solution in the strength of two per cent., which gives a faint rose tint that becomes bleached if acids are produced, and intensified if alkalies are formed. Phenol-phthalein solutions give a purple-red with alkali, and are bleached by acid. A number of such cultures should always be made simultaneously, as the result may vary in individual tubes, and control tubes, not inoculated, should always be placed with them, as occasional changes occur from the absorption of ammonia or carbonic acid, etc., from the air.

The formation of indol, characteristic of certain organisms, is tested by the occurrence of a rose-purple tint in Dunham or ordinary peptone bouillon, when a few drops of concentrated sulphuric acid are added to a culture kept twenty-four to forty-eight hours in the incubator. This reaction requires the presence of nitrites as well as indol, and therefore, if it does not appear upon the simple addition of sulphuric acid, one or two drops of 0.02 per cent. solution of sodium nitrite should be added. Some bacteria produce nitrites from simple peptone solutions, while others do not. The test is open to the fallacy that volatile ammoniacal compounds are formed in the air where gas is being burned, and when absorbed into water are changed into nitrites, so that the presence of nitrites in a bouillon does not indicate that they are formed by the action of bacteria, unless control tubes, which have not been inoculated, remain free from them.

Petruschky recommends the employment of a whey obtained from milk, and colored with litmus (Lakmusmolke) for testing these reactions, but the media are more difficult to make than Dunham's solution.

Milk.—The growth of some of the organisms in milk is highly characteristic, and should always be studied; the presence of coagulation or not, the time at which it occurs, etc., should receive attention. Besides plain milk, milk to which litmus is added is also a valuable reagent.

Reduction of Nitrates.—This reaction is characteristic of a large number of water bacteria, and is stated by Frankland to afford a valuable means of diagnosis between otherwise identical forms. It is best studied in a solution containing 0.5 of calcium nitrate, 0.5 of inverted sugar, 400 c.c. each of solutions of 1 per 1,000 phosphate of lime, 0.2 per 1,000 sulphate of magnesia, and 0.1 per 1,000 chloride of calcium, 400 c.c. of which mixture, with 1 gramme of peptone and 15 grammes of calcium carbonate, are added to 4 litres of distilled water. To estimate the amount of nitrate reduced to nitrite is a somewhat complicated process, and can only be satisfactorily done by reducing the terms of ammonia and employing Nessler's test. A more simple and ready means of obtaining the same result would apparently be the employment of the phenyl-hydrazin test, but for some reason or other this test does not give reliable results in the presence of peptones (in the writer's experience), although a slight reduction can be made out. The fault appears to be due to some influence produced by the peptone. The working of the test is complicated by the possible absorption of ammonia or nitrates from the air; precautions should therefore be taken against this by cultivating in stoppered bottles kept in a pure atmosphere.

Water.—The power or not of multiplying in plain water is characteristic of a number of water bacteria, and distinguishes them from other allied forms. Sterilized tap-water is to be preferred as a culture medium to distilled water, as the latter seems to exert an injurious influence upon some organisms, possibly by promoting osmotic changes.

Flagella of bacteria are stated by Strauss to be stained by mixing the material thoroughly with a drop of carbol-

fuchsin diluted with four times its bulk of water, and examining directly under a cover-glass. This method gives good results with the cholera vibrio, but not with the typhoid bacillus.

The most reliable stain for flagella is Loeffler's method. See article "Bacteriological Technology."

Relation to Temperature.—A simple method of roughly establishing the temperature relations of an organism is to make three sets of cultures in bouillon, potato, and agar, and keep one at the room temperature, say 20° C., another near 30° C., and the third at 37° C. The rate and abundance of growth being noted in each case. This shows roughly the optimum, or most favorable temperature, as compared with the others, and in the case of water bacteria the cultures at 37° C. usually remain sterile. Subsequently, more accurate and elaborate tests can be made, and the thermal death-point noted, by exposing cultures to various temperatures for fixed lengths of time.

Relation to Oxygen.—The greater number of bacteria found in water belong to the strictly aërobic organisms, and cease to grow visibly when their supply of oxygen is cut off. The most simple method of testing this is that suggested by Koch, of making a streak culture upon gelatine, which has just become solid, upon a plate or in a Petri dish, and laying upon it a thin plate of mica, which should be sterilized in a flame immediately before use. With strictly aërobic organisms no visible growth occurs, though by the microscope a number of minute colonies may sometimes be seen, which are enabled to grow to a certain extent by the oxygen or air enclosed in the gelatine. If the colonies do not grow visibly, they are certainly neither anaërobic nor facultative anaërobic, and it is therefore unnecessary to study further their capacities in this direction.

The employment of the deep culture is also a simple method of showing the necessity, or otherwise, of oxygen to the bacteria. A stab culture is made in a gelatine tube, and another tube of liquefied gelatine or agar is poured above this. The culture is thus prevented by the upper gelatine from the access of air, and if truly aërobic no growth occurs. These tests are open to the fallacy that small quantities of air are apt to be absorbed by the gelatine, even if boiled just previous to use, which suffice to insure a slight growth even in aërobic forms. A better method is that (of G. Roux) where the air is excluded by a mixture of vaseline, 98 parts, paraffine, 2 parts, for cultures at room temperature, or of vaseline, 90 parts, white wax, 8 parts, and paraffine, 2 parts, for cultures kept at body temperature. Previous to inoculation the tubes should be boiled, so as to drive out all oxygen, and then cooled. The same result can be attained by pouring a layer of sterilized oil over the upper surface of the medium in the tube. In inoculating the cultures it is best to introduce the seed by means of a sterilized capillary glass tube. Where the anaërobic bacteria are to be studied, exclusion of oxygen can be obtained either by absorbing the oxygen in the tubes or plates by means of alkaline pyrogallic solution (Buchner), by passing in hydrogen gas (Fränkel), or by exhausting with the mercury pump (Schotelius). Hesse has recently introduced a simple method, which was also partly anticipated by Marchmann, in which hydrogen gas is passed in under mercury. The methods of Kitasato with flat flasks or rolled tubes, which are filled by means of a rubber stopper, perforated by sealed glass tubes; or the method of Botkin, where the plates are placed under a bell-jar, sealed by vaseline or glycerine at the bottom, are all more or less inconvenient. In isolating anaërobic bacteria it must be remembered that a large number of aërobic germs are present in the original water inoculated, so that it is necessary to purify the first culture by plating it a second or even a third time under anaërobic conditions before the aërobic organisms are completely got rid of.

The cultures of anaërobic bacteria is made much easier by the addition of some reducing substance, such as glucose, 2 per cent., or formic acid, ½ per cent., to the medium, as this lessens the amount of free oxygen present at the commencement (Kitasato).

Gas Production.—The formation of bubbles of gas in gelatine or bouillon cultures is an important biological character. Anaërobic and semi-anaërobic organisms tend to produce gas, and do so most readily when sugar of some sort is present. Its peculiarity offers a ready means of distinction between typhoid bacilli and most other members of the colon group, as the former do not, and the latter do produce gas in saccharine bouillon.

For testing the formation of gas, Theobald Smith recommends the use of Einhorn's saccharometer tubes. These are filled with bouillon containing one to two per cent. of grape-sugar and sterilized. After inoculation they are placed in the incubator, and at the end of twenty-four hours marked gas production occurs, and bubbles collect at the closed end. The distinction between typhoid and colon bacilli by this means is declared by Smith to be absolute, the typhoid variety never producing gas, while the colon invariably does so. Dubief, in asserting that both organisms produce gas, appears to have been in error; the production of gas is checked when the medium becomes too strongly acid, but proceeds again upon neutralizing. The writer has found the test a reliable one, and remarkably uniform in its action.

Rate of Growth.—The property of growing rapidly or slowly should be noted in the description of an organism, and it is better, as far as possible, to give some absolute standard, such as the diameter of the superficial and deep plate colonies, etc., at a certain time after inoculation. In most descriptions the only statement made is that an organism grows rapidly or slowly, which does not convey a very clear idea, though it is better than nothing. When it is stated that an organism grows rapidly, it is meant that colonies attain their maximum development within a few days or a week. In organisms which grow slowly, little growth is visible during the first few days, and the colony takes several weeks to mature and assume its most typical form.

Metabolism.—The chemical changes produced by water bacteria are, as yet, but little understood.

Liquefaction of Gelatine—Peptonization.—Evidence of this action depends upon the formation of a peptonizing ferment, which, when isolated, or when the cultures containing it have been sterilized, is capable of liquefying gelatine, independently of any bacterial growth. Though striking and characteristic of certain forms of bacteria in plate and tube cultures, the liquefaction of gelatine is a minor biological property. It was, at one time, supposed that the liquefying colonies were the putrefactive ones, whose presence would therefore form an objectionable feature in the water. This view is no longer held, as it is known that many putrefactive organisms do not liquefy gelatine, while many which do not tend to cause putrefaction possess this power.

Other Chemical Products.—The water bacteria are capable of forming a large number of chemical products which belong, usually, to a class of the alcohols, especially the higher alcohols, the aromatic compounds, indol, etc., extractives, amides, and other ammoniacal combinations; lactic, butyric, succinic, and proprionic acids. The subject is too large to be entered upon here, and we do not know to what extent the products which characterize the water bacteria in artificial media are formed under natural conditions.

In some cases the products of certain compounds are highly characteristic of particular organisms, and form a valuable means of diagnosis; for instance, the absence of indol in bouillon cultures of typhoid was stated to distinguish it from bacillus coli. The presence of indol reaction in bouillon cultures of the cholera vibrio is also considered a valuable diagnostic point, though a number of other allied forms also produce it. Bacillus fluorescens putridus produces a strong trimethylene odor resembling that of pickled herring. A form of bacillus fluorescens liquefaciens, studied by the writer, produced a strong cyanogen odor in gelatine cultures, but the vapor evolved gave a reaction somewhat different from that of cyanogen gas.

A group of organisms, chiefly marine, form phosphorescent products; this luminous substance being in some species produced most abundantly in cultures kept at very

low temperatures, from 0° to 4° C., and made in media containing two and a half per cent. of chloride of sodium.

Pigment Formation.—The power of certain forms to produce pigment affords a very valuable diagnostic feature. The colors produced are most various and afford a ready means of recognizing the species; unfortunately descriptions of the tint of color are very difficult to convey in words, and thus far no satisfactory way of recording the nature of the pigment has been worked out. In certain organisms, for instance, bacillus prodigiosus, the chemical characters of absorption spectra of these pigments have been recorded, and their solubility in different media noted. Unfortunately, this has not been done in the case of many organisms. In describing a pigment in this manner, besides the color, the solubility in water, alcohol, ether, benzine, etc., should be noted; also the effects of heat and of alkalies and acids. These give a rough insight into the chemical nature of the product. In the case of the yellow pigments, a difficulty is encountered through their being almost insoluble. The fluorescing pigments are particularly hard to describe. The chromogenic bacteria may be roughly classified, from the color they produce, into (1) violet, (2) blue, (3) green, (4) fluorescing (mixed green and yellow), (5) yellow, (6) orange, (7) red, and (8) brown, forming fairly distinct groups. These groups are very difficult to subdivide simply by means of the shade produced, owing to the difficulty of obtaining an absolute standard of color. Probably the only method by which this could be accomplished is the quantitative determination of the spectrum obtained from them by reflected light by means of Abney's disks. This consists of a rotating disk, in which by means of a sector various amounts of yellow, red, green, etc., can be cut off; the resulting shade being expressed numerically in terms of so many degrees red, so many yellow, etc., when a color is obtained corresponding to that under consideration. For studying the color formation the potato and agar cultures are most suitable, as it is produced there most abundantly. The division of bacteria into pathogenic and chromogenic groups is not scientific, since some of the chromogenic bacteria have pathogenic effects.

Pathogenesis.—The testing of the pathogenic properties of water bacteria is a field but little worked in; the methods employed consist in inoculating a large number of the usual animals, rabbits, mice, guinea-pigs, etc., with the organisms. The fact that few of the water bacteria grow well at body temperature probably accounts for the very small number of instances in which the pathogenic characters have been shown to be present. In a few instances bacteria have been found in water which are fatal to the amphibia. Certainly fishes, frogs, and turtles would appear to be more suitable subjects for experiment than warm-blooded animals. Bacteria from the slime at the bottom of lakes, rivers, and reservoirs have often been found to possess pathogenic properties when inoculated into white rats.

In some instances toxic bodies have been isolated from the cultures of water bacteria which are capable of producing poisonous effects. Such organisms have been called "toxogenic" by Vaughan.

Special Methods for Diagnosis of Pathogenic Organisms.—The methods specially recommended for detection of cholera and typhoid bacilli in water have already been described in another part of this article (p. 1029). Certain species and races of bacteria not originally pathogenic, become so by being passed through a series of animals.

Nitrifying Bacteria.—For isolating the organisms producing nitrification the use of special media is necessary. Successful results were first obtained by the dilution method in solutions containing sulphate of ammonia (0.4 p. c.), sulphate of magnesia (0.05 p. c.), phosphate of potash (0.1 p. c.), carbonate of soda (0.6 to 1 p. c.) in distilled water. The presence of even slight traces of gelatine, agar, or other organic substances is sufficient to stop the growth, and therefore the ordinary culture media are quite inapplicable. A suitable solid medium was obtained by Winogradsky by adding soluble silicate of soda, water-glass, which is a thick, syrupy liquid that becomes gelatinous on the addition to it of numerous mineral salts, notably those which were above mentioned as forming a suitable culture medium for the nitrifying organism. The medium is prepared by diluting the ordinary commercial water-glass with three times its volume of water. One hundred cubic centimetres of this are agitated with hydrochloric acid, and the mixture is placed for three days in a dialyzer, care being taken that the acid shall be in excess. At the end of three days, during the first of which the dialyzer is left in a current of tap-water, and the rest of the time in distilled water frequently changed, the solution is ready for use. It should give no turbidity with nitrate of silver, showing the absence of hydrochloric acid. It can be sterilized by boiling, and preserved in a flask stopped with cotton wool; to this is added sulphate of ammonia, 0.4; sulphate of magnesia, 0.05; phosphate of potassium, 0.1; chloride of calcium, a trace; carbonate of sodium, 0.6 to 0.9; distilled water, 100. The sulphates, with the chloride of sodium on the one hand, and the phosphate and carbonates on the other, are to be dissolved and sterilized separately, and the solutions mixed after cooling. For cultures Petri dishes answer very well.

The silicate solution is first evaporated to half its volume, and tested repeatedly as to its powers of gelatinizing by adding to 2 or 3 drops one drop of the saline solution in a watch-glass. The gelatinizing commences in five minutes, and should be sufficiently stiff at the end of ten or fifteen minutes to prevent the disappearance of an impression made upon its surface. After this it is not well to continue the concentration, as this is liable to cause the precipitation of granules and scales of insoluble silicic acid. The silicate solution is then distributed in a small pipette in the Petri dishes, and there is added about one-half or one-third its volume of the saline solution inoculated with the culture material; the two liquids being carefully mixed. At the end of several minutes a slight opalescence indicates coagulation. If desired, the inoculation can be made in the plate immediately after having mixed the two liquids. For streak cultures, inoculation should be made when the coagulation is complete. Carbonate of magnesia may be employed instead of carbonate of sodium, as it yields a somewhat more transparent medium.

The cultures begin to grow in this jelly at the end of from one to two weeks. The plates must be carefully preserved from dessication, and can be studied for from four to six weeks. Although the silicate jelly forms a very unfavorable medium for the development of ordinary bacteria, their growth is not absolutely excluded, and if introduced with the seed material they are not destroyed. They do not form colonies large enough to be confused with the nitro-bacteria, and appear at a much earlier date than the latter. The purity of a culture may be proved by its inability to grow upon ordinary media, and only those which then remain sterile can be considered as nitro-organisms. Though employed by Winogradsky this medium was suggested by W. Kühne.

In the older method of obtaining cultures by dilution a series of stoppered bottles containing the saline liquid was prepared, and these were inoculated from the substance containing the nitrifying organisms. By diluting the original material a thousand-fold or more and seeding a number of flasks with extremely minute portions of the culture, a series of daughter-cultures are obtained in some or most of which nitrification can be detected. By inoculating portions of these simultaneously into fresh saline media and ordinary gelatine media, cultures are ultimately obtained which produce nitrification, but give no growth in gelatine. These are pure cultures of the nitro-bacteria.

Sleskin recommends the following method: 100 c.c of water-glass, dialyzed and reduced to about $\frac{1}{4}$ its volume by boiling (the concentration must not be carried to the point of inducing turbidity), is diluted with sterilized concentrated solutions, (a) of the sulphates, and (b) of phosphate of potash and sodium carbonate. By mixing the different components of the saline solution directly with the silica the danger of turbidity and precipitation

is lessened. By increasing the proportion of the mineral salts a firmer coagulation is obtained, but the power of supporting the growth of nitro-bacteria is somewhat lessened.

Description of Species.—A diary is kept of the cultures made, with the dates, so that a glance at the page will show the work to have been attended to on a particular day, and will afterward serve as a reminder whether it has been done or not. Thus with specimen No. 9 an entry like this was made :

23. VI. 91.	From colony on gelatine plate.	Made. Gelatine plate.
25. VI. 91.	From Plate of 23. VI. 91.	Made. F. P. G. Plate (to test purity). F. P. G. tube. Cell culture. Culture made under mica. Deep tube culture.
30. VI. 91.	From Plate of 25. VI. 91.	3 Agar tubes, at 37°, 22°, 18° C. 3 Potato, at 37°, 22°, 18° C. 3 Bouillon, at 37°, 22°, 18° C. 2 Serum. 2 Milk, at 37°, 18° C. 2 Litmus milk, at 37°, 18° C. 2 Corallin broth, at 37°, 18° C.

In this way a preliminary examination of a new organism can be accomplished in about a week, after which its more detailed study, the accurate determination of its chemical changes, thermal death-point, etc., can be resumed, if desired.

Scheme for Description of a New Species.—Name, habitat, morphology, staining, spore formation, motion, cell culture, gelatine plate, gelatine tube, agar, potato, serum, bouillon, other media, rate of growth, temperature, relation to air, fermentation, pigment formation, pathogenesis.

A great drawback in qualitative work is the difficulty of comparing the results of one observer with those of another. Slight differences in the media employed, irregularities in temperature, and other minor matters of technique make it extremely risky to say whether the forms described in one country or town by one person correspond with those described elsewhere by another. The variability of bacteria and their tendency to form races, in which minor deviations from the standard type become permanent, makes it a delicate matter to decide what constitutes a distinct species. The difference between these varieties of the same species sometimes appears to be greater than that between atypical forms of different species. This variation has been critically studied by Adami, who considers that atypical forms may be looked upon as races when permanent. The value of these variations cannot, however, be definitely settled by individual work; what is needed appears to be a cooperation of different observers, and the comparison of races or varieties obtained from different localities, by which means the personal equation would be, as far as possible, eliminated. A fine field appears to be offered here for collective investigation.

The qualitative study of water bacteria sometimes affords a far more delicate means of detecting contamination than mere quantitative analysis. The writer, in the case of a very foul stream of water entering a large river, was able, at a distance of two hundred feet from the junction of the waters, to predict with confidence that contamination still existed, although the total number of bacteria present per c.c. at that point did not exceed the number met with in the purer water on many occasions, and was not sufficiently large to arouse suspicion. The pure water, however, contained on that occasion colonies of bacillus fluorescens liquefaciens sufficient to form thirty per cent. of the total number of colonies. In impure water the proportion of B. fl. liq. was less than half of one per cent. of the total. Where a high degree of contamination existed the proportion of B. fl. liq. was five to ten per cent., and at two hundred feet out was still below twenty per cent., thirty per cent. being again reached at four hundred feet, where the water was pure. A parallel set of samples, collected for chemical examination, showed undue amounts of nitrates and chlorides at one hundred and two hundred feet, but not at four hundred —a result identical with the bacteriological.

Migula, as a result of over 400 analyses of well and spring waters, obtained statistics of the relative number of species: twenty-one per cent. of the samples only contained one to four species; and one-fourth of these only contained a single species. The remaining seventy-nine per cent. contained five or more different species, and of these fourteen per cent. contained more than ten species. According to Migula a water containing more than ten species per c.c. is to be considered as more or less contaminated by organic impurities. An inverse ratio existed between the number of colonies developed and the number of species present: for instance, in samples where 50 colonies per c.c. develop 4 times only a single species was found; 5 times, 2 species; 6 times, 3 species; 5 times, 4 species; 3 times, 5 species; twice, 6 species; 3 times, 7 species; twice, 8 species; 3 times, 9 species; once, 10 species, and never more than 10. On the other hand, when 10,000 to 50,000 colonies develop per c.c., never less than 4 species were present. According to the usual theory, that only water containing about 50 colonies per c.c. should be considered pure, only one-tenth of the waters examined by Migula would be approved by the simple enumeration of the colonies; whereas, if the presence of ten different species per c.c. be taken as the extreme limit for a pure water, only one-eighth of the samples could have been classified as impure.

Certain species were found characteristic of stagnant waters: Micrococcus ureæ, M. cinnabarius, B. fluorescens putridus, B. erythrosporus, B. fluorescens liquefaciens, B. ureæ, B. mesentericus vulgatus, B. tremelloïdes; while the forms most frequently met with in running water were: M. coronatus, M. radiatus, M. viticulosis, B. luteus, etc. It must be freely admitted that these results of Migula are open to the objection that examinations were made on extremely small bodies of water. The organisms mentioned as characteristic of stagnant waters have also been found by others in large bodies of water of unquestionable purity.

The relation between the number of species and that of the colonies was as follows :

No. of species per c.c.	Number of colonies per c.c.							
	0 to 60.	60 to 100.	100 to 600.	600 to 1,000.	1,000 to 5,000.	5,000 to 10.000.	10,000 to 50,000.	Over 50,000.

Pathogenic Bacteria have been recognized in water by a number of different observers, whose statements may be accepted without reserve. Koch found the cholera germ in the water of a tank in India, where the disease was prevalent among the natives who consumed the water. Rietch found cholera bacilli in the sea-water outside the harbor of Marseilles during the prevalence of an epidemic. G. Roux found tetanus bacilli constantly present in the water-supply of Lyons, and Miquel in the water and sewage of Paris. Septic organisms, and organisms causing specific pathogenic effects when inoculated into animals, have been found in the water and sewage of numerous cities. Vaughan detected a series of

bacteria pathogenic for rats in numerous waters from Michigan.

As pathogenic bacteria all grow at the temperature of the body, by making cultures in bouillon, or by keeping bouillon cultures at these temperatures, the water bacteria tend to be excluded, while the pathogenic forms persist, so that, after a few transplantations the isolation of the pathogenic forms is rendered comparatively easy.

The study of the effects of immersion in water upon pathogenic germs has given valuable results. It has been shown that the cholera vibrio under such circumstances usually dies out in the course of a few days, and is incapable of multiplying in ordinary drinking-water: typhoid bacilli do not show any marked powers of growth in water, but retain their vitality for a considerable time, even three months or more. Tetanus bacilli and the pathogenic micrococci do not lose their vitality and powers of infection rapidly in sterilized water, but do so if the water is impure. Anthrax, when not in the form of spores, soon loses its vitality and powers of growth. Sea water acts injuriously upon the virulence and vitality of pathogenic organisms, notably tetanus bacilli. Under suitable conditions of temperature and nutrition, bacteria are capable of recovering the powers which they have lost by immersion in water.

P. F. Frankland has shown that anthrax bacilli may form spores in water. Many water bacilli possess antagonistic powers over anthrax in water.

Of all infectious diseases, typhoid fever and cholera are the ones having most importance in relation to water-supplies.

Cholera.—The relation of cholera epidemics to drinking-water is a matter about which there has been considerable dispute. Koch advocates the simple and intelligible view that water contamination was the main source of infection in cholera epidemics. At the same time infection by other means, such as contamination of food-supply, cooking-utensils, bedding, clothing, rags, etc., or from soiling of the fingers, was not denied. Pettenkofer, on the other hand, has insisted throughout that epidemic infection cannot take place in this direct manner except when a specially favorable "local disposition" prevails in the infected district. He designates this local disposition as Y; the specific germ as X; and the individual predisposition as Z; all three forming the unknown factors in what he terms the equation of a cholera epidemic. This theory he recently put to the test by swallowing, at Munich, cultures of cholera bacilli obtained from the Hamburg epidemic of 1892; having at the same time taken sufficient alkali to guard against the destruction of cultures by the gastric juice. The same experiment was also carried out by Professor Emmerich, his assistant. The fact of their surviving the operation was claimed by these gentlemen to show conclusively that they owed their salvation entirely to the absence of the element Y, peculiar to the vicinity of Hamburg. Those who have no special object in supporting the claims of the unknown factor Y, will probably be inclined to infer from the fact that both Pettenkofer and Emmerich suffered from severe rice-water diarrhœa, colic, cramps, etc., with abundance of cholera bacteria in the stools, that cholera was actually produced in these cases, and that the mild course of the disease was to be explained by the insufficient dose administered and the absence of previous gastro-intestinal disturbance, or by the microbes having lost their virulence in the process of cultivation. Professor Pettenkofer has apparently done nothing more than afford an additional proof, if one were needed, that the comma bacillus is capable of producing cholera, as a result of his somewhat rash experiment. That cholera bacilli are subject to great variations of virulence was proved by Hueppe and Wood, who showed that their power of producing the poisonous chemical substance to which the symptoms of cholera are due, becomes increased when grown under anaërobic conditions, and furnished with abundant albuminoid nutriment; while in the presence of oxygen, and with a diminished supply of albumin, this organism, becoming more hardy, loses its power of producing the specific toxin. As the cholera bacillus, when occurring in a drinking-water supply, is under the aërobic conditions, its toxic virulence is probably low.

A most convincing argument in favor of the part played by drinking-water in conveying the cholera infection, is the fact that cholera does not become epidemic in cities having a pure drinking-water supply secured from contamination. That the soil water becomes so influenced by Pettenkofer's factor, Y, as to determine the outbreak or not of a cholera epidemic, is a matter lying, apparently, beyond proof. That certain epidemic influences determine the spread of cholera, and that these vary in different seasons for different localities, seems established beyond doubt. That in 1892 cholera did not spread epidemically in England, the United States, and Paris, although isolated cases existed, is a remarkable fact, and seems to show that some epidemic element was wanting. That cholera has never been known to appear epidemically in certain great centres of travel, for instance, Hanover, although isolated cases repeatedly lodge there, is equally remarkable. Whether this immunity is due to the exertions of the sanitary authorities, or whether it depends upon natural peculiarities of the soil, etc., we cannot say; but since it seems clear that, given a good supply of drinking-water, cholera can be prevented from becoming epidemic, there is every reason to assume that labor and money expended in securing good water-supply will not be thrown away.

Special methods for the detection of cholera bacilli can scarcely be said to exist, though the rapid growth at body temperature in bouillon can be taken advantage of (Schottelius), and a preliminary bouillon culture made, from which, at the end of twelve hours, plate cultures can be prepared; the more numerous the plates, the more likelihood of finding the cholera organism.

Koch has lately introduced a ready means of isolating cholera spirilla from water. Peptone and salt are added so as to form one per cent. of each in the water to be examined. This liquid is placed at 37° C., and in a few hours if cholera germs are present they will be found abundantly at the surface. The liquid should be strongly alkaline, one per cent. standard alkali being used.

Strongly alkaline gelatine is also stated to favor the growth of the spirillum. Placing 200 c.c. of the suspected water in the incubator, after adding 10 c.c. of peptone bouillon, favors the growth of the cholera and other spirilla.

The spirillum described by Finkler and Prior has also been found in water.

Recently, C. Gunther has described under the name of vibrio aquatilis, an organism closely allied morphologically to the cholera vibrio, and in which also the gelatine plate presents an appearance liable to be confounded with cholera (*Deutsche med. Wochenschr.*, December 8, 1892).

Weibel (*Centralblatt. f. Bact.*, xiii., p. 117), has also described a vibrio resembling the cholera organism, and Bujwid (*Cent. f. Bact.*, xiii., p. 120) describes two vibrios which also resemble it. Heidel (*Wiener med. Presse*, No. 46, 1892) describes two allied vibrio forms isolated from water.

Koch found, in a large number of samples of water, thirteen spirilla species which somewhat resembled the comma bacilli, but were distinguishable from them without much difficulty.

All the above organisms produce much more turbidity and liquefaction in gelatine plates than the cholera germ. They all give the cholera-red reaction with mineral acids.

Spirillum Choleræ (Koch).—Found in water by Koch, Nicati, Lubbarsch, Loeffler, and Fränkel.

Aërobic and facultative anaërobic, liquefying, motile spirillum. Grows best at blood temperature. Slightly curved rods with rounded ends; 0.8 μ to 2 μ long, and 0.3 to 0.4 μ wide. Sometimes somewhat circular or S-form. Under unfavorable conditions of growth, they form long spiral filaments. Numerous flagella at each end of the rods. In old cultures swollen and distorted involution forms. Spore formation doubtful. Decolorized by Gram's method.

On gelatine plate, at end of twenty-four hours, deep colonies small and white. Grow toward the surface and produce liquefaction funnel, in the shape of an air-bubble, at the bottom of which the colony is seen. Under low power, before the appearance of liquefaction, colonies are white or pale yellow and coarsely granular, with nodular outline. After liquefaction, colony surrounded by a rosy halo, with double contour, caused by the sharp margin of the funnel. A lively motion is seen among the granules composing the colony, and a dark mass of bacteria lies in the centre with a paler periphery. In gelatine tube, slight liquefaction, causing an air-bubble at the top of needle-track at end of twenty-four hours. In forty-eight hours, cup-shaped depression at surface with narrow area of liquefaction half-way down the needle track, and white deposit at the bottom. On agar, a moist, white, glistening growth. On potato, at room temperature, no growth; at 35° C., thin brownish growth. In bouillon, abundant growth, with turbidity at end of twelve hours. Later, membranous surface pellicle. On serum, slight liquefaction. In milk, good growth, without change of medium. Does not grow in acid media. Slight growth (?) in sterilized water, and vitality preserved for several months. In non-sterilized water, dies in a few days. In peptone bouillon, indol reaction; reddish-violet color, upon adding sulphuric acid, at the end of twenty-four hours. Pathogenic for guinea-pigs, when introduced by the mouth, if gastric juice be neutralized. Produces an infective septicæmic condition in animals, with a rapid fall of temperature, when inoculated into the peritoneum.

Typhoid.—Abundant proof has been furnished at various times that typhoid is communicated by drinking-water. The most conclusive proof of typhoid being spread by drinking-water obviously lies in the recognition of the typhoid bacillus in the supply, and this has now been done in over fifty instances by reliable observers, since Klebs first detected what he erroneously took for typhoid bacilli in the sediment of the Zürich reservoir in 1884.

Unfortunately, the value of these observations is considerably lessened by the fact that many waters contain bacilli which very closely resemble the typhoid organism; and further, this organism itself is subject to great variation, and shows a great tendency to the formation of aberrant races.

The typhoid bacillus is one of a group of organisms of which the type is the bacillus coli, and while typical cultures of both of these show well-marked points of distinction, intermediate forms occur where it is difficult to decide to which group they belong.

In the colon group we may include, for convenience, besides the bacillus coli and typhoid bacillus, a large number of allied forms, best known as pseudo-typhoid, some of which are among those described by Weichselbaum under the name of *Bacillus aquatilis sulcatus*. These forms have the common feature of producing gelatine-plate colonies, which in their early stages resemble typhoid, but which can on further study be distinguished from it. The separation of those which subsequently produce a visible growth on the potato, liquefaction of gelatine, fluorescence, or some such appearance, offers no difficulty. Cassadebat has, in a valuable memoir, given the diagnostic tables of what he calls the pseudo-typhoid organisms, including under this head those colonies which resemble typhoid in early plate cultures. As he makes these, however, to include such widely different forms as bacillus fluorescens liquefaciens and bacillus violaceus, it is evident that his use of the term pseudo-typhoid is altogether too loose.

If, instead of including all these heterogeneous species under the heading of pseudo-typhoid bacilli, we restrict the term to those organisms which can only be distinguished from typhoid by prolonged study in parallel cultures, through the occurrence of slightly more coarse and abundant growth, etc., or other minor points, we narrow down the subject materially, and our diagnosis has really only to be made between these and the organisms of the colon group. Among the latter a large number can be readily excluded by their forming visible colonies on potatoes; by not possessing flagella; or by not producing gas in saccharine bouillon.

The presence of motility, the absence of a scum in bouillon cultures, non-liquefaction of the gelatine, and failure to stain by Gram's method, are characters possessed in common by the typhoid, colon, and pseudo-typhoid groups.

The production of acute septicæmia in animals is characteristic of an allied species group, that of the hog-cholera organisms, and distinguishes them from the pseudo-typhoid forms.

The diagnosis between the pseudo-typhoid organisms proper and genuine typhoid forms, is an extremely difficult matter, and up to the present no single universal test has been discovered. It is a striking feature of the literature on this subject that the more carefully and extensively the observations are recorded, the more conservative are the conclusions drawn.

The Germans have taken an agnostic standpoint, and rarely admit that the organisms found in suspected water have been generally typhoid bacilli. The German results in suspected waters have generally, therefore, been negative. The French observers, on the other hand, have gone to the other extreme, and frequently claim to have found typhoid bacilli in drinking-water.

Quite recently, Arloing and Gabriel Roux have promulgated the heterodox view, that no sharp distinction exists between typhoid and colon bacilli, but that the latter, under certain conditions, become transformed into the former and are capable of producing typhoid. This statement, brought forward at the International Hygienic Congress at London, in 1891, met with general disapproval at the hands of the other bacteriologists present, and quite rightly, as no one has disputed since the time of Snow, that to introduce typhoid in a new district, a case of typhoid fever is first necessary; that the introduction of one case of fever could permanently modify the conditions outside the body in such a manner as to enable the bacillus coli to produce typhoid, is absurd.

At the same time, two circumstances bearing on this head have not received sufficient consideration:—1. A number of anomalous cases, which are diagnosed as typhoid fever from the fact that they present a fever of the continued type, with or without intestinal disturbances (the simple continued fever of the older writers, Flint, and others), may often not be typhoid fever at all, but are due to fermentative changes set up by the bacillus coli, and constitute a form of intestinal sepsis. 2. Where typhoid contamination of water exists, since it can only be naturally brought about by fecal pollution, the bacillus coli must be present. A water contaminated by typhoid is necessarily contaminated also by bacillus coli (Péré).

The frequency with which organisms of the colon group are met with in water is such as to cause these to be regarded as belonging to the class of water bacteria; at the same time it must be borne in mind that organisms of the colon type are not peculiar to man, but almost identical forms occur in animals and birds. It is possible that they also occur in the amphibia and fishes, as normal dwellers in the intestines possibly also in the crustacea, vermes, and other lower forms inhabiting the water; so that an abundant source of supply of these organisms in water and soil is assured, without assuming that they occur quite independently of animals.

Infection through drinking-water has probably been overrated as a factor in the production of typhoid, and too great a tendency exists to look upon this as constituting the only danger. Where infection can clearly be traced to a pollution of the water-supply having an obvious connection with a case of typhoid fever, there need be no hesitation in assuming that this has really taken place; but, at the same time, typhoid can be equally readily communicated by food-supply, milk, kitchen utensils, soiled linen, and furniture; and, probably, by the air.

An undue suspicion attached to drinking-water may lead to other sources being overlooked, more especially

the possibility of infection being communicated by the surroundings of the patient in the sick-room. The non-recognition of this tendency of infection in typhoid fever has led to too great latitude in the reporting and isolation of cases, and the carrying out of general hygienic precautions in stamping out an epidemic. Among troops in Landrecies, Mauberge, and Avesnes, in 1891, Arnould found that measures directed to the disinfection of the drinkiug-water had no effect; whereas, isolation of the patients, disinfection of the apartments and linen, etc., promptly resulted in its disappearance. If infection is due to drinking-water, attention directed to this point alone will promptly remove it. Probably the too general prevalence of typhoid fever is to be attributed, not to contamination of drinking-water, but to the tendency among practitioners and health officials not to regard typhoid as highly infectious, which it really is. The long incubation period, the uncertainty of diagnosis, and the fact that the susceptibility is almost confined to ages between fifteen and thirty, has led to the ignoring of the factor of contagion in typhoid. In all cases of typhoid, disinfection should be thorough and general, and not confined to the stools alone.

The influence of soil and drainage in determining the spread of this disease, in connection with drinking-water and otherwise, is difficult to estimate. Pettenkofer, of course, insists that his *Y* is the agency at work, and that the pollution of the ground-water is the real source of danger. He considers that a lowering of the ground-water level following an unusual elevation, leads to an increase of bacteria in the soil, and their penetration to a greater depth. However, during the epidemic at Berlin, referred to in another part of this article, observations made upon the level of the ground-water showed that it was stationary previous to and throughout the epidemic.

The infection of typhoid fever through air has been strenuously opposed by many authorities. That it does occur, however, the writer has no doubt whatever. In one epidemic, in which he was himself a sufferer, where 14 cases with two deaths occurred, among eighty individuals living on a large quadrangle in which a drain had recently been opened, all the cases, with one exception, occurred among those whose windows opened upon the courtyard where the opening was made. The exceptional case occurred in a person who had amused himself by sitting during his leisure hours on the edge of the drain, and chatting with the laborers, one of whom also became ill. As all the eighty persons were drinking the same water and eating together, there appears no reason for the peculiar distribution of this epidemic unless the air was the means of contagion. The epidemic occurred during the summer, at a time when the windows were left open at night, and the two fatal cases occurred in the two individuals whose rooms were nearest to the drain, and who, presumably, got the largest dose of contagion.

Special Methods.—The means of recognizing typhoid bacilli in drinking-water, are detailed in the sections, "Methods," and "Species." Extreme caution should be observed in pronouncing an organism, found in water, to be the genuine typhoid bacillus, and such an opinion should only be given after prolonged comparison between undoubtedly genuine typhoid organisms and those obtained from the water. The points of difference which exist between the typhoid cultures themselves are less than those between the suspected organism and the genuine cultures.

The detection of the typhoid bacillus in drinking-water was first accomplished in 1885, by Dr. Moers, in a sample of well-water obtained from Muelheim-on-the-Rhine, and yielding four thousand to five thousand bacteria colonies per c.c. The second occasion upon which typhoid was found was by Dr. Michael, in Dresden, in 1885. On a third occasion where typhoid bacilli were found in water, the investigators were Dreyfus, Brisac, and Weidal, in Menilmontant, France, on October 13, 1886. Shortly afterward, Brouardel and Chantemesse discovered the typhoid bacillus in the cistern of a house in Clermont-Ferrand, where typhoid appeared. In 1887 Boemer detected typhoid bacilli in the water of a spring near Greifswald; and since then numerous investigators have obtained similar results.

Special Methods Employed for Isolation of Typhoid Bacilli and Allied Forms.—The examination of water for typhoid bacilli frequently gives negative results, owing to the extremely small quantity examined. Where a few drops or a few cubic centimetres are used for each sample, it is evident that, even when two hundred or three hundred individual observations are made, the total amount of water inspected amounts to only a few litres—an infinitely small quantity to adopt as an indication of an entire water-supply.

Improvements in method have been made in three directions: 1, To enable a larger quantity to be examined; 2, to use media favorable to the growth of the typhoid bacillus and unfavorable to that of other organisms, especially the water bacteria; 3, to employ better means of identifying the organisms fouud.

The separation of the typhoid bacilli from larger samples of water is facilitated by combining the advantages of (1) and (2). One of the methods suggested is to remove the bacteria from the water by sedimentation (Finkelburg), so as to obtain that in a smaller compass, and then adopt the ordinary plate methods. The use of a centrifugal apparatus for concentrating sediments has been recommended, but does not accomplish what has been claimed for it.

Liquid Media.—Péré recommends the following method: Into a sterilized litre bottle or flask 100 c.c. of sterilized neutral beef stock are introduced, and 600 to 700 c.c. of the water to be analyzed; 50 c.c. of a ten per cent. solution of peptone, and 20 c.c. of a five per cent. solution of carbolic acid are added, and the flask is filled to the litre mark with the suspected water. This is divided among five or ten sterilized flasks (ordinary bottles will answer), and kept for twenty-four hours at a temperature of 35° C. Growth is indicated by the appearance of turbidity, usually commencing at the end of fifteen or twenty hours, but sometimes not for thirty hours, if the contamination is slight. When the turbidity is well marked the cultures are made in bouillon containing one per cent. of carbolic acid, one per cent. of beef broth, and five per cent. of peptone. On the appearance of turbidity cultures are again made, either at once in gelatine, in order to isolate the species, or after cultivating in one or two successive changes of phenol bouillon. The only forms surviving are the members of the colon group, namely, B. coli, typhoid bacillus, or some pseudo-typhoid forms.

This method is one of the most convenient of a series which have been devised, all depending in principle upon the alleged capacity of the typhoid and colon bacilli to grow in carbolized bouillon. The advantage it possesses is that larger quantities of water can be dealt with, five to ten litres being readily handled in the course of a single observation.

Several methods had been previously published, notably that of Rodet, who isolated the typhoid bacillus by keeping bouillon cultures at a temperature of from 42° C. to 45.5° C., at which temperature the ordinary water bacteria rapidly die out.

Chantemesse and Weidal, Vincent and Thoinot were the first to employ phenol bouillon; the first important publication being that of Brouardel and Chantemesse. The method employed here was that of adding five drops of a five per cent. carbolic acid solution to 10 c.c. of bouillon, and seeding five to fifteen drops of the water for examination in each of a series of tubes. The object of diluting the water to various degrees was that, when only a few of the typhoid or colon bacilli are present, the cultures sometimes remain sterile. The writer has employed graded dilution in connection with Péré's method, by introducing the carbolic acid by a burette, after the litre of water bouillon has been divided into five portions of 200 c.c. each, and distributing the 20 c.c. carbolic solution among the flasks in proportions of 2, 3, 4, 5, and 6 c.c. respectively.

Thoinot and Lois concentrated their material in examining for typhoid, by passing the water through the Chamberland filter and examining the sediment deposited in it.

Parietti employed an acid carbolized bouillon made by adding to 10 c.c. of neutral bouillon from three to nine drops of the following solution: Carbolic acid, 5; hydrochloric acid, 4; water, 100. The typhoid bacilli withstand the addition of the acid well, and if the beef tea becomes cloudy in twenty-four hours the probability is that they are present.

Solid Media.—Several methods have been suggested for obtaining solid media upon which typhoid bacilli would grow, and which would at the same time be unfavorable to other germs. Chantemesse announced that this could be effected by the simple addition of 0.2 per cent. carbolic acid to nutrient gelatine. This method was tested by Holz with somewhat unsatisfactory results, and the proportion of 0.2 per cent. was found to hinder the growth of the typhoid bacilli. Holz found that with pure cultures of typhoid bacilli, 0.1 per cent. phenol was the maximum amount tolerated, and 0.07 per cent. gave a better growth of typhoid bacilli. The discrepancy between the statements of different authors possibly depends upon the volatility of carbolic acid, the addition of which should be made after the sterilization is complete, and just before the cultures are to be used.

A method suggested by Riedel, in which 0.1 per cent. down to 0.02 per cent. of trichloride of iodine was added to gelatine, was also shown by Holz to have a tendency to check the growth of typhoid bacilli.

Dunbar, as a result of experimental studies, considers the methods of Chantemesse, Parietti, and others, for promoting the growth of typhoid bacilli at the expense of the other organisms of water, to be unreliable, since these methods at the same time hinder the growth in the typhoid germ itself, as compared with its growth in non-carbolized or alkaline media. Further, he states that its development in the special media is more retarded than that of the closely allied pseudo-typhoid forms.

A valuable nutritive medium suggested by Holz is potato gelatine. This is made by grating peeled potatoes upon an ordinary bread-scraper, squeezing the juice through a cloth, and allowing it to stand twenty-four hours in a refrigerator, by which time it assumes a dirty brown tint and becomes quite turbid. After filtration the filtrate is heated for half an hour in a steam sterilizer and again filtered. To the clear deep yellow filtrate ten per cent. of gelatine is added, the mixture steamed three-quarters of an hour, filtered, and poured into test tubes, which are to be sterilized on three successive days.

The potato gelatine so obtained is clear, transparent, and pale brown in color, with a strongly acid reaction (10 c.c. requiring 2.4 to 3.2 decinormal alkali). Upon this medium typhoid bacilli grow readily and somewhat more luxuriantly than on ordinary gelatine, while ordinary water-bacteria and most saprophytes do not grow upon it. Moulds grow slightly. The special advantage of this medium is that the plate cultures are not liquefied by the end of from three to five days, and the plates can therefore be kept longer under observation, for the purpose of watching the growth of slow-growing colonies, among which the typhoid bacilli are to be reckoned. Holz recommended the inoculation of the suspected water direct into this medium.

He was able to detect typhoid bacilli in an extremely foul sample of ditch water at the end of twenty-eight days, but only applied his method to water experimentally contaminated, and was unable himself actually to isolate typhoid bacilli by means of it from any water supply examined. He recommends the addition of 0.05 per cent. carbolic acid to the potato gelatine where extremely foul water is to be examined.

Uffelmann employed a gelatine acidified with citric acid until 10 c.c. require 1.4 c.c. of decinormal sodium carbonate for neutralization. After filtering, 2.5 mg. of methyl violet are added per c.c., coloring the medium a faint blue: the growth of typhoid bacilli intensified the blue color.

Grancher and Deschamps employed gelatine colored by the aniline mixture suggested by Noeggerath, made as follows:

Saturated aqueous solutions of			methylene blue..	2 c.c.
"	"	"	gentian violet....	4 c.c.
"	"	"	methyl green....	1 c.c.
"	"	"	crysoidin	3 c.c.
"	"	"	fuchsin	4 c.c.
Distilled water.....				200 c.c.

After standing two weeks the color produced upon absorbent paper should be deep gray or bluish black, which can be adjusted by adding, if necessary, the tints which are weak. Ten drops of this solution are added to 10 c.c. of gelatine, which is sown with the organism to be studied. The characteristic of the typhoid bacillus is stated to be the production of a brilliant purple-violet in the colonies, while the gelatine in the neighborhood is decolorized; but Vaughan has met with other forms giving the same results.

Gasser recommends the addition of twenty drops of saturated aqueous solution of fuchsin to a tube of agar, which becomes gradually decolorized by the growth of the typhoid bacillus. This reaction is not well shown when the medium is freshly prepared, but is more uniform if kept some weeks before inoculation.

All these methods have the common advantage of separating typhoid bacteria from other widely different forms, thus getting rid of the latter; but they have also, without exception, the drawback that they furnish an excellent medium for those bacteria which closely resemble typhoid, particularly the pseudo-typhoid organisms, in the strict sense of the term. These grow as well or better than the typhoid bacteria in Holz's potato gelatine, in the various phenol bouillons, and in Parietti's medium; they produce, moreover, as marked or more marked color changes in the various colored solutions or jellies. This decolorization depends simply upon the acid production of the bacteria, it being well known that basic anilines are decolorized by acids, and there is nothing distinctive in it, since the form which produces the most acid will produce the most powerful decolorization.

Hazen and White have recommended isolating typhoid bacilli from the common forms in water, by cultivating on agar-plates at a temperature of 40° C., at which very few other forms develop.

We therefore find that, while we have at our disposal a number of processes by any one of which, or by combination of several, we can easily obtain for further study what is either the typhoid germ itself or one of a number of allied species or races which closely resemble it, we have no universal medium or rule-of-thumb process by which it can be differentiated from these. To have attained certainty in the first step of the process is nevertheless a considerable advance.

A fact not usually known is that culture in the special phenol and other media mentioned above induces racial changes in the bacteria, and causes them to take the characteristics of the typhoid bacillus aud preserve them for a long time, and often through many generations.

I have employed as the most convenient means of isolating typhoid and pseudo-typhoid forms, the following combination of methods: 1, Péré's method, employing one or more litres of water as seeding material; 2, passage through phenolized bouillon in tubes; 3, plates from the latter upon Holz's gelatine; 4, plates on ordinary nutrient gelatine.

Diagnosis of Typhoid and Colon Bacilli from Closely Allied Forms.—The exact determination of these organisms is a matter requiring prolonged study. No universal rule can be laid down, but the organisms must be carried through a series of cultures, and compared with typhoid bacilli from an undoubtedly genuine source.

As the typhoid bacilli show certain tendencies to variation (Babes) and to the formation of races and natural varieties, several cultures from different sources should be selected for this comparison:

A. *Diagnosis of Typhoid from Colon Bacilli.*—The distinction between a typical typhoid culture and a typical

colon culture is so sharp and distinct that it is difficult to confuse them. The following points should be verified in any particular case: 1. Typhoid has active independent motion; colon only molecular or oscillating motion. 2. Typhoid in media containing sugar does not produce gas or destroy the sugar; colon does. 3. Typhoid produces no indol; colon does. 4. Upon potatoes typhoid grows invisibly; colon grows with a thick gray-yellow colony, staining the rest of the potato a grayish brown. 5. The typhoid bacillus has numerous flagella (from four to sixteen); the colon has no flagella at all, or only from one to three. 6. Milk is coagulated promptly by B. coli but not by B. typhi.

While these differential points hold good for typical cultures of both organisms, they are not true of the varieties, and aberrant types or races can be met with where it is impossible to make a diagnosis. As a general rule, it may be stated that the peculiarities of the typhoid bacilli are negative in character, while those of the colon are positive; so that any organism which produces gas, coagulates milk, and grows visibly upon acid potatoes, may be set down as almost certainly not typhoid.

B. *Diagnosis of Typhoid from Pseudo-Typhoid Bacteria.*—In this procedure all the resources and patience of the bacteriologist are called into play. Organisms which are identical with typhoid cultures through most of the comparative tests may often with patience be excluded by attention to some minor point. The degree of acidity produced; the intensity of the color reactions; the minor details of microscopic appearance; the power of withstanding temperature; the power of multiplying in simple water—are all points any one of which affords the requisite information.

Especially important are: 1. The chemical changes produced in bouillon, milk, aniline solutions, etc. These have been used by Cassadabat for the exclusion of three forms very closely allied to typhoid and simulating it perfectly in gelatine culture. 2. The date at which colonies appear is also stated by Cassadabat to be of prime importance. A large number of pseudo-typhoid forms, though having the same appearance in ordinary gelatine and potato gelatine as the genuine form, grow more rapidly and appear earlier on potato gelatine. 3. When the observations are extended over several weeks or months, changes appear which might be overlooked at an earlier period; one of these is a very late liquefaction of the gelatine, coming on from the 20th to the 120th day of the culture. The typhoid bacillus never under any circumstances liquefies gelatine, so that this is an unfailing cause for exclusion of a suspected form.

It has been noticed that a tendency to late liquefaction is especially observed in cultures which have been originally isolated by means of carbolized bouillon, and it seems that a lasting alteration in the life processes is developed by this medium, which alteration only disappears after successive cultivations in other substances. A culture in which liquefaction first appeared after three months was found upon successive passages through ordinary gelatine to liquefy at a much earlier date, having apparently regained its property of peptonizing.

The appearance of the growth in old cultures is always more delicate and less vigorous in genuine than in pseudo-typhoid forms. The spurious bacteria usually form a more abundant and coarse surface colony, and give a heavier growth along the needle track. In old Esmarch tubes or stab cultures a continued increase of the colony after from four to six weeks is indicative of a pseudo-form.

The brownish pigment which forms a smoky halo in the neighborhood of the colony near its surfaces, and the small clumps of whitish crystals which jet out from the needle track in old stab cultures, are usually more marked and abundant in pseudo- than in genuine cultures.

The growth of agar gives little information, though, as a rule, it is more delicate in the case of the genuine than in that of the pseudo-varieties. The growth on potato does not as a rule afford any assistance, though of course any organism which grows visibly on acid potato may be promptly excluded. The formation of a distinct scum upon bouillon is indicative either of an impure culture, or that the genuine typhoid organism is not present.

The reason for the scant success attending the examination for typhoid bacilli often may lie in the fact that the original water contamination was merely transient, and the bacilli had disappeared by the time when the outbreak of cases directed attention to the water.

C. *Colon Bacteria.*—The distinction between genuine colon bacteria and the spurious forms is even more difficult than between the former and typhoid, owing to the fact that the colon organism presents even more variation than the typhoid one, and that, as stated elsewhere, a number of slightly varying forms of the colon bacillus occur in the fæces of other animals besides man, which forms have not yet been systematically studied. It is almost impossible to say whether an organism resembling a colon bacillus is derived from the human fæces or not. As far as we know, the tendency to a grosser and more abundant growth is the only distinction between genuine and pseudo-colon bacteria. The inoculation into animals may possibly lead to more accurate information in future upon this head.

In conclusion, the best advice which can be given to those engaged in this work is that it is always safer to adopt a conservative point of view, and not to admit the genuine nature of organisms except on very strong grounds.

Bacillus Typhi.—Aërobic and semi-anaërobic, non-liquefying, motile bacilli. 1 to 3 μ long and 0.5 to 0.8 μ wide, with rounded ends. Sometimes they form long threads. They are decolorized by Gram's method. Unstained vacuoles are sometimes seen in rods. Spore formation is doubtful. Numerous thick flagella. Grows best at blood temperature.

On gelatine plate, small white colonies are found at the end of forty-eight hours. Under the microscope the colonies are oval or spherical, granular, and yellowish brown. At the end of three or four days the surface colonies form a grayish white, delicate, pearly layer, with wavy transparent margins and opaque central nucleus. Surface is marked with fine lines and furrows. In old colonies extension is never very great, and growth is never thick and coarse. In gelatine tube, white rounded colonies develop along the needle track, with delicate, pearly, translucent extension on surface. Growth is most abundant in the upper part. In older colonies a smoky brown discoloration appears just beneath the surface in the colony itself and in the surrounding gelatine. This color subsequently extends along the needle track; sometimes small white bunches of needle-shaped crystals project from the deeper part of the growth. The appearances vary considerably in different cultures, owing to the establishment of races. There is some discrepancy as to the exact appearance of the typical colonies as described by the best observers. On agar, there is an abundant white semi-translucent growth. On potato, the growth is invisible, producing a moist, shining appearance at the surface, of a stringy, viscous consistency; it is most characteristic upon strongly acid potatoes. On alkaline potatoes, a thin yellowish growth may be developed. In bouillon, there is simply a turbidity. There is no production of gas in media containing sugar. The bacilli do not produce indol. In milk they grow abundantly, with slight production of acid. They do not coagulate the medium or change its appearance. In serum, their growth is scanty, in the form of transparent, shining, isolated patches. They grow well in bouillon containing from 0.05 to one per cent. carbonic acid. They grow on potato gelatine, with or without carbonic acid; and also in acidulated bouillon (Parietti's solution).

Tetanus.—The occurrence of the tetanus organism in water has no special pathological significance; being present in the soil, it naturally finds its way into water. Infection of wounds through water is unknown. The peculiarity of the tetanus organism is that it only becomes able to infect under certain conditions, such as the presence of its toxic product, or the simultaneous introduction of certain saprophytes, or the presence of retained pus.

The bacillus of *malignant œdema* has also been isolated from water (Pasteur).

Vaughan has described, under the name of B. venenosus, a series of water organisms having what he calls *toxigenic* properties. Some of these resemble closely the typhoid bacillus.

The significance of the experiments of Vaughan and others upon the toxic and pathogenic bacteria in water, when tested on animals, cannot yet be estimated. Certainly, ninety-nine per cent of the organisms found in water have no toxic powers whatever, although the investigation of the pathogenic qualities of the ordinary water bacteria is a matter requiring further study.

Staphylococcus aureus has been frequently found in surface waters. The micrococcus associated with Biskra boil has also been found.

Ernst has described a bacillus producing septicæmia in frogs and other cold-blooded animals at low temperatures, 10° to 15° C., but losing its virulence if the animals are kept in water at 24° C. The name *B. hydrophilus fuscus* applied to this organism by Sauerelli, has been retained instead of the original one of *B. ranicida*, suggested by Ernst.

Globig reported the outbreak of a singular epidemic in a regiment of marine artillery, which was traced to swimming in unclean water. The disease somewhat resembled an abortive form of typhoid. In the description given by Jäger of this epidemic, out of 20 cases, with three deaths, a characteristic organism was obtained from the blood in the early stages; and from the organs—the liver, spleen, and kidneys—in one fatal case. According to Jäger, this organism is specific of the disease, and from its characters he has named it the B. proteus fluorescens. It was found abundantly in water of a small contaminated stream, near a point where the affected troops bathed in the Danube. The same organism had caused an infectious disease among fowls, and the contamination was apparently traced to contamination of the water by the dead bodies of the affected fowls. The evidence on this head is not particularly convincing.

Goître.—Goître has been known to prevail in districts where the water-supply contains large amounts of lime, but the relation which that bears to the etiology of the disease is extremely obscure. Lustig claims to have been able to produce goitre in horses, by making them drink water that came from Aosta, a region where goître is extremely prevalent; he also claims to have isolated a specific bacillus from this water, which, for some reason not very clear, he regards as the cause of the disease. Experimental proof of the production of goitre by inoculation or feeding with pure cultures, is not yet forthcoming.

Yellow fever has been thought to be due to contamination of drinking-water supplies, but there is no evidence to the effect, and Sternberg is opposed to this view.

Although experimental evidence is not yet forthcoming, it is highly probable, judging from the capacity shown by attenuated cultures of pathogenic organisms to become virulent after passage through a series of animals, that some of the ordinarily non-pathogenic water bacteria may acquire pathogenic powers when passed through many successive animals (Adami).

Wyatt Johnston.

WEIGHTS AND MEASURES. The Pharmacopœial Convention of the United States which met at Washington, May 5, 1890, ordered that the weights and measures employed in the Seventh Revision of the Pharmacopœia must be those of the Metric System exclusively. Hence the old English Apothecaries' Weights and Measures which were abolished in England in 1825, and which never had been adopted by law in the United States, have now lost their firm hold upon physicians and phar-

macists, and the use of the Metric System will necessarily be adopted and taught in medical and pharmaceutical schools to the exclusion of the obsolete units.

Another decided change which has taken place since the publication of the earlier volumes of the REFERENCE HANDBOOK OF THE MEDICAL SCIENCES is the adoption of metric prototype standards as the ultimate standards from which all weights and measures used in the United States for any and all purposes are now derived. The American National Prototype Standards of the metre and kilogram, made of irido-platinum, were received by the Government of the United States from the International Bureau of Weights and Measures at Paris in 1890, and placed in the custody of the Office of Standard Weights and Measures at Washington. In 1892 they were formally adopted by that office as the ultimate standards to which all comparisons of metrological values are referred, and the old Hassler standards are, therefore, no longer used.

The value of the American National Prototype Standard Metre is identical with that of the International Standard Metre derived from the *Mètre des Archives*, and the American National Prototype Standard Kilogram, like the International Standard Kilogram, is derived from the *Kilogramme des Archives*.

Theoretically, the litre is equal to one cubic decimetre, or 1,000 cubic centimetres; but the actual litre is the volume of one kilogram (actual International Kilogram) of pure water at the temperature of its maximum density, *in vacuo*. Thus, although the litre and the cubic decimetre are probably not identical values, the litre and the kilogram are commensurate with reference to water at 4° C. and *in vacuo*.

The American *yard* is now defined to be equal to $\frac{36,000}{39,370}$ metre; and the American commercial *pound* (avoirdupois) is defined as being equal to $\frac{700,000,000}{1,543,235,639}$ kilogram.

The American *liquid gallon*, which is designed to be 231 cubic inches, is now derived from the new American National Metric Prototypes on the assumption that the *theoretical* kilogram (the weight of one cubic decimetre of water at its maximum density, *in vacuo*) and the *actual* kilogram (the metal prototype) are identical values. As the metre contains, according to latest authority, 39.3700 inches, and the kilogram 15,432.35639 grains, one cubic inch of water at maximum density, *in vacuo*, weighs 252.-892 grains, and from this value is found the weight of 231 cubic inches. The present actual liquid gallon of the United States is, therefore, according to the Office of Standard Weights and Measures, the volume of 3,785.-434 grams (or 58,418.1444 grains) of water at the temperature of maximum density weighed *in vacuo*.

Oscar Oldberg.

WHOOPING-COUGH. The large number of articles on whooping-cough that appear yearly in the medical journals show very plainly that the subject is far from a cut-and-dried one, and that there is much still to be learned. Out of all this mass of literature, the references to which are given at the end of this article, we must try to pick out that which is new and valuable, and to discover, if possible, what advances have been made, if any, in our knowledge of this disease since the HANDBOOK was published in 1888.

With the exception of a few interesting records of complications, I shall confine myself almost entirely to the consideration of the etiology and treatment, the two subjects about which, particularly the latter, much has been written.

ETIOLOGY.—When the original article on whooping-cough was written, the discoveries of Affanassieff of what he claimed to be the specific bacillus of the disease had just been announced. In the same year Sseintschenko [90] confirmed these observations, and, although he finds the bacilli in the sputa, they are, as might be expected, mixed with numerous others from the mouth. In a later article [89] he concludes: "1. The bacillus of Professor Affanassieff is specific. 2. Bacilli may be found in the sputum about the fourth day of the disease; in some cases earlier. 3. They multiply in the tissues of the body, and as they increase the severity of the disease increases. 4. The bacilli disappear before the entire cessation of the attacks of coughing, or when the paroxysms are reduced to from two to four daily. 5. With complications such as, for example, a catarrhal pneumonia, there is a great increase in the number of whooping-cough bacilli found in the sputum. 6. A pneumonia developing under these circumstances differs from ordinary attacks of catarrhal pneumonia. 7. The bacillus of whooping-cough is of value not only in etiology and diagnosis, but in the prognosis of the disease."

Burman thinks that, whatever the etiology may be, the severity of the nocturnal paroxysms points to the preponderance of the nervous over the catarrhal element. The nervous mechanism inducing an attack would be more active during the night, owing to the insufficient oxygenation of the blood caused by the shallow respirations during deep sleep.

COMPLICATIONS AND SEQUELÆ.—Like other acute infectious diseases, whooping-cough has been followed by nephritis. Scheltma [79] reports a case in a child of two years. Mettenheimer [58] also has reported a case. Mircoli [59] had a singular experience in this respect, finding in one epidemic of whooping-cough albuminuria in from ten to twelve per cent. of the cases, and a mortality of five to six per cent. He believes that this state of things is not rare, and is generally overlooked, and that the urine should be examined from time to time during the course of the disease. He thinks, however, that the nephritis is of a mechanical rather than infectious nature, and is caused by venous stasis, due to the obstruction of the vena cava from the violent paroxysms of coughing.

Of complications due to cerebral disturbance, Alexander [1] reports a case of blindness, with symptoms of cerebral compression and death, due, it was believed, to cerebral anæmia. In a second case, not fatal, blindness occurred, due to optic neuritis from meningitis. Fritsche [30] reports paralysis of the right facial nerve, unilateral spasms, hæmianæsthesia, and aphasia, with recovery. Möbius [60] relates a case of paralysis coming on six weeks after the onset of the disease.

Troïtzky [94] reports three cases, all ending favorably, where whooping-cough was accompanied by considerable mental disturbance, difficulty in talking, and more or less paralysis due to disturbances in circulation and to subsequent morbid changes in the brain. Jacoby [42] reports two cases of temporary blindness of brief duration, due, it was thought, to œdema of the brain.

Emphysema was spoken of in the main article as a complication due to the forced expiration with closed glottis. A case of this sort is reported by Pernet. [71] An extraordinary case of complete subcutaneous emphysema beginning after a paroxysm of whooping-cough is related by Croker. [15] The child, five years old, developed a swelling of the neck below the jaws after a hard fit of coughing. This swelling gradually increased and spread over the entire body, so that the neck, cheeks, chest, arms, legs, and trunk resembled a series of huge bladders. The scalp was blown out in front and at the sides, the scrotum was inflated to the size of a large ostrich egg. The case prove fatal in five days.

INCUBATION.—As bearing on the incubation stage, Perskind reports a case where a child began to have whooping-cough five days after birth, there being several other cases in the family. As the mother was not suffering from whooping-cough herself, it is not likely that the disease was acquired *in utero*.

TREATMENT.—It is interesting to study the various waves of enthusiasm or fashion in the use of different drugs or modes of treatment for whooping-cough. A specific has not been found, although this has been proclaimed, and is still being proclaimed from time to time. Of the etiology that whooping-cough is a germ disease, we are reasonably sure, although the specificity of the bacillus of Affanassieff may be doubted. This knowledge of the etiology is the first step to the rational treatment

of any disease. We should naturally expect to find, therefore, antiseptics to be the drugs most in vogue. It has been said that "no particular antiseptic should be inferior to all others. Either they are all useful in destroying the presumed microbe, or else none of them have any great value." This certainly is not true, for it is apparent that different vegetable germs, as well as different members of the animal kingdom, are affected differently by different poisons or antiseptics. While the organism of malaria may be destroyed by quinine, it is not much influenced by mercury, the reverse being true in the case of syphilis. Belladonna is comparatively harmless to rabbits, but extremely poisonous to men. If one antiseptic has no effect on the course of whooping-cough, it does not follow that another will be equally ineffectual. For this reason an incentive is given for the trial of various antiseptics, and also of various methods of administration described in the original article—by the mouth, by nasal insufflations of sprays or powders, or by insufflations into the throat, or by topical, nasal, pharyngeal or laryngeal applications. Let us now take up *seriatim* the various drugs recommended since the HANDBOOK was first published.

Antipyrin.—As I have already remarked, treatment directed to the general condition of the patient to enable him to resist the disease while it ran its course, is far better than any treatment which at the same time lowers the vitality of the patient. One of the most striking examples of this is antipyrin, first used and greatly extolled in 1887 and 1888, by Sonnenberger, Genser, and Laborderie, as almost a specific for whooping-cough, and one free from danger. Geffrier, Griffith, and Jacques Bey also speak favorably of it. Guaita employed nasal insufflation of the drug in addition to its internal administration.

The great dangers of depression with collapse and cyanosis from antipyrin began later to be recognized—although Sonnenberger stated he never had this result—and has debarred, and with reason, many from using antipyrin for a disease which is in itself depressing. Its advocates have diminished in number, and some have even stated that the disease was not shortened, or the paroxysms reduced in number. Thus Baginsky and Monti had entirely negative results from the use of antipyrin. Tuczek treated his own child of four with six grains of antipyrin three times daily. At the end of the third week he became soporose, with violent convulsive attacks, the heart's action became weak and frequent, the temperature subnormal and the pupils dilated, all of which was attributed by Tuczek to the antipyrin. Notwithstanding this, Ree[75] reported that in the convulsive stage antipyrin would abate the disease on the third or fourth day, and Hare,[36] and also Muttler,[64] even in this last year maintain that there is no remedy for whooping-cough so satisfactory as antipyrin. The former gives two grains to a child of ten years every three hours, until an effect is obtained, and then every four or five hours. Cyanosis of the face and finger-nails is to be carefully watched for, and the drug to be stopped. He says that cyanosis first appears under the thumb-nail. Dubusquet-Labordie[20] used antipyrin in three hundred cases with good results, one hundred and ninety-seven cases recovering very rapidly.

Bromoform is a drug that has come into use for whooping-cough only since the HANDBOOK was published. It is a heavy, colorless liquid of the composition $CHBr_3$, thus resembling chloroform and iodoform. It is an anæsthetic. As it is decomposed by light it must be kept in dark-colored bottles. Stepp[91] believed it superior to any other remedy for whooping-cough, using it with satisfaction in seventy cases, diminishing the number of paroxysms, and curing the disease in three weeks. He used the following formula:

℞. Bromoform..... gr. x
Alcohol..... ʒ j
Syrupi..... ʒ ss
Aquæ..... ʒ iij
Sig. One teaspoonful every hour.

Senator[84] is particularly enthusiastic about this remedy, using it in one hundred cases, and getting good effects as early as the second or third day.

Neumann[66] found in twenty-five cases that bromoform cut short the disease and reduced the number of paroxysms.

Krieger[43] used it in nine cases with great success, and Fischer[28] in sixteen cases, also with success, seventy-five per cent. being discharged well in from two to three weeks.

Earle,[22] of Chicago, reports eight or ten cases treated with bromoform, with good results.

Nauwelaers,[66] although he considers bromoform almost a specific, sounds a note of warning, as it acts powerfully on the nerve-centres, and advises small doses at first, to be gradually increased. He considers its action in whooping-cough that of an antispasmodic, not a germicide.

Schippers[81] considers bromoform of great value and gives the following doses: six months to one year, ♏ ij., three times daily; from one to two years, ♏ iij.; two to three years, ♏ iv.; three to four years, ♏ v.; four to seven, ♏ vj. to vij., in a spoonful of syrup, three times daily.

An unfavorable view is given by Üllmann,[95] who compared the result of treatment with bromoform with that of an indifferent drug and found no difference, with the exception that bromoform, as a narcotic, sometimes influenced the child unfavorably.

The writer's experience with this drug has been very satisfactory up to the present time.

Ouabaïne, an alkaloid from the roots of the Ouabaïo, of the formula $C_{30}H_{46}O_{12}$, is another new remedy for whooping-cough, first used practically in this disease by Dr. Gemmell,[33] of Glasgow. He treated forty-nine cases with no ill effects, and with the result of markedly diminishing the paroxysms, and shortening the course of the disease. Dr. I. L. Porteus[72] has used it in this country with similar good results.

The dose is very small, $\frac{1}{100}$-grain every three hours, in a child of five years, $\frac{1}{400}$-grain being given to a child of fifteen months by Dr. Porteus. The flow of urine is increased and the appetite improved. Its action is said not to be cumulative. The toxic effects to be looked for and avoided are slowing of the pulse and respiration, particularly the latter. Further trial of this drug is certainly indicated.

A curious and odoriferous treatment is recommended by Chibret,[13] who sprinkled the room and the poor patient with *iodoform*—and with good results.

Wild Thyme in infusion, Thymus vulgaris, has been used with wonderfully good results by Neovius.[67] A cure is generally obtained within fifteen days.

As was to be expected, *Peroxide of hydrogen*, which seems to arouse so much enthusiasm and is reported to cure anything in which there is a suspicion of a germ, has been found an infallible remedy for whooping-cough. Dr. B. W. Richardson, also Dr. J. Mount Bleyer, recommend it.

I have made a list of the special papers on the treatment of whooping-cough published in the last four years, and classified them according to the drug used. Those on the use of antipyrin head the list, which is as follows, and is of interest in showing the tendencies in treatment:

Antipyrin, 15.	Nitrate of silver, 2.
Bromoform, 11.	Ouabaïne, 2.
Resorcin, 8.	Antifebrin, 2.
Carbolic acid, 4.	Sulphur, 2.
Vaccination, 4.	Peroxide of hydrogen, 2.
Belladonna, 3.	Quinine, 2.
Phenacetine, 3.	Ergot, 2.
Benzoin, 2.	

Cocaine, oxymel scillitique, oil of cypress, naphthalin, iodoform, eucalyptus, ozone, hydrate of turpentine, thyme, and chloride of gold and silver, each have one article.

Surely one might say, after reading the favorable results recorded by different writers on the treatment of

this disease, whooping-cough is plainly one of the most amenable of all diseases to treatment, and moreover, there is a great number of drugs that will produce the desired result. The opposite of this, however, is much nearer the truth. The stage in the disease when treatment was begun, the mildness or severity of the epidemic, and the fact that whooping-cough often runs an atypical course, should always be borne in miud.

Although there may be some slight advance in our treatment of whooping-cough since the HANDBOOK was first published, there still remains much room for improvement in the management of this troublesome disease. *Charles W. Townsend.*

WINES, SPIRITS, AND BEER. The following additions to the article published in Vol. VIII., giving some information not easily available to the general reader, and bringing the statistics of the subject as nearly as possible up to the date of publication, will be found very useful.

THE PASSE-TOUT-GRAINS AND THE ORDINARY WINES OF BURGUNDY.—The glorious names of the grand growths of Beaune, Pommard, Volnay, Nuits, Chambertin, etc., are universally known and appreciated to the utmost, as they deserve, but there is a class of Burgundy wines, not so well known and less admitted into foreign consumption, but which is worthy in every respect of being brought forward and becoming an article of constant and daily use wherever wine is drunk. We mean the Burgundian *vins ordinaires*, the cheap dinner wines, usually drunk in France with an admixture of water.

These wines have, in the first place, the merit of being more within the reach of modest purses than the first growths, which are costly luxuries, and their quality entitles them to a special place in the list of the cheap wines that are now grown nearly everywhere in the world where the climate and the soil permit the cultivation of the vine. Ordinary Burgundy, in common with French wines in general, possesses a perfect cleanliness of taste, and it has besides, without being heavy or heating, a sapidity and a freshness which make it an agreeable, healthful, and refreshing beverage. These qualities, added to the body peculiar to its robust constitution remind one, to a certain extent, of the grand growths.

In making a careful study of the wines of the district, we find a complete series ranging without a break from the cheapest up to the first growths.

Before describing the ordinary wines, properly so called, we should give a word to the *Passe-tout-grains*, which should be classed as "grand ordinary" or "little fine" wines, as they occupy a place between the grand wines and the ordinary.

The *Passe-tout-grains* are produced from vineyards planted with both the superior Pineaus and the ordinary Gamays—the more Pineaus there are in the vineyard, the more the wine will approach the class of "fine" wines. It is the mixture of the two sorts of grapes that gives this wine its name of *Passe-tout-grains* (including both sorts).

Nothing is better than a good *Passe-tout-grains* as an intermediate wine between the grand growths and the ordinary wines. It is the *grand ordinaire* of the tables of the rich, and the good *Extra* of the modest Burgundian home, being both a fine wine and an ordinary one, as it combines the virtues of both the Pineaus, which give bouquet and elegance to the fine wines, and the Gamays which produce the others. The former give it its delicacy and perfume, the latter its freshness and solidity. It is like a marriage between a nobleman and a peasant's daughter; the children of the union possess the fresh and sturdy health of the mother and the aristocratic grace and elegance of the father.

This wine is not scarce; it is grown all over the *côtes*

(hills) of Beaune and Nuits. On the hills of Beaune, the Parish of Meursault deserves special mention for the extent of the vineyards devoted to the production of *Passe-tout-grains*. On the hills of Nuits, all the district between Alexe, Corton, and Prémeaux, near Nuits, as well as the vineyards that stretch from Gèvrey-Chambertin to the gates of Dijon, are given up to the growth of this wine. It is highly esteemed in Burgundy, and the Burgundians eagerly seek to produce it in all localities where the soil and exposure would not suffice for the production of the grand wines.

The ordinary wines are divided into three classes, the *ordinaires* of the *côtes, arrières-côtes* (upper hills), and the *plaine* (flat country). These wines do not possess the delicacy of the *Passe-tout-grains*, but they have in their stead body and strength, together with a fresh and agreeable fruity taste.

The *ordinaires* of the côtes are the best and the highest priced, and come in the scale of Burgundy wines immediately after the *Passe-tout-grains*. They are the product of the Gamay grapes gathered among the lower hills, and the best of them are made in the region of the *Passe-tout-grains*.

In the district called the *Côte de Beaune*, Corpeau, Puligny, and Meursault produce many Gamay wines; in the *Côte de Nuits*, Serrigny, Corgoloin, Comblanchier, and further north, in Perrey, Brochon, Fixin-Couchey, Marsannay, and Chenove excellent Gamays abound. As these wines are produced in the *Côte de Beaune* or the *Côte de Nuits*, they are generally sold respectively as "Beaune" and "Nuits," which must be considered as abbreviations for *ordinaires* of the *Côte de Beaune* and *ordinaires* of the *Côte de Nuits*.

The *ordinaires* of the *Arrières-Côtes* possess the same characteristics as the *ordinaires* of the Côtes, but with less richness and less body. They are proportionally cheaper. They are excellent wines for habitual drinking, particularly in the good years, and an amateur who has grown accustomed to them will not use any other wine for his "*ordinaire*." These wines are grown throughout the extent of the Arrières-Côtes. The most important localities are Villars-les-Fontaines, Magny-les-Villers, Echevronne, in the *Côte de Nuits*, and Nantoux, Mandelot, Meloisey, St. Romain, Larochepot, and Nolay, in the *Côte de Beaune*.

The wines of the plains are weaker than those we have mentioned, and have no interest for the export trade.

This short sketch of the cheaper wines of Burgundy may serve to show that in addition to the antique renown of her grand vintages, she may claim the modest merit of growing excellent ordinary wines, admirably fitted for transportation, and richly deserving the attention of foreign markets.

The wine production of the principal countries of the world since 1874 has been as follows:

WINE PRODUCTION OF THE WORLD.*

YEAR.	France.†	Spain.	Jerez.‡	Italy.	German Empire.	Austria.	Hungary.	Croatia-Slavonia.	Portugal.	Douro.	Madeira.	United States.

* Quantity in American gallons. † Including Algeria. ‡ Not including Sanlucar, Port St. Mary's, Moguer, etc.

PRESENT AVERAGE ANNUAL PRODUCTION.

Russia	75,000,000	Turkey, including Cyprus	65,000,000	Argentine Republic	30,000,000
Greece	39,600,000	Servia	72,800,090	Chile	39,520,000
Roumania	53,000,000	Bulgaria	70,000,000	Cape of Good Hope	2,642,000
Switzerland	28,420,000			Australia	3,000,000
				Tunis	2,500,000
				Persia	739,000
				Canaries	3,950,000

The following table shows the quality of Bordeaux, Champagne, and German wines in each year since 1867:

	Bordeaux.	Champagne.	German.
1868....	Generally good.	Fine.	Good.
1869....	Very fine.	Superior.	Ordinary.
1870....	Varying.	Very good.	Fair, light.
1871 ..	Elegant, thin.	Ordinary.	Inferior.
1872....	Ordinary, fair.	Good ordinary.	Middling.
1873....	Bad.	Middling.	Fair.
1874 ...	Fine.	Very fine.	Fine generally.
1875....	Very good.	Generally good.	Inferior, light.
1876....	Bad.	Fair.	Good.
1877....	Well made, elegant.	Fair.	Inferior.
1878 ...	Very fine generally.	Good.	Fair, light.
1879....	Inferior.	Below medium.	Hard, bitter.
1880....	Thin and poor.	Good ordinary.	Part good.
1881....	Good, ripens slowly.	Medium.	Irregular.
1882....	Bad, mildew.	Ordinary.	Thin, sour.
1883....	Medium.	Fair, some good.	Good.
1884....	Much good.	Very great.	Better than 1883.
1885....	Inferior.	Good ordinary.	Middling.
1886....	Very bad.	Ordinary.	Fine, best since 1868.
1887....	Good.	Bad, mildew.	Medium, small,
1888....	Generally good.	Poor.	Poor to fair.
1889....	Very good.	Fair.	Fair.
1890....	Very fair.	Good.	Middling.
1891....	Good.	Good.	Miserable.
1892....	Very fine.	Grand.	Very good.

PRODUCTION OF LAGER BEER.—The production of the ten largest lager-beer breweries in the world in 1888 was:

Brewery.	Where Located.	Barrels.
Anheuser-Busch	St. Louis	465,943
Spaten	Munich	413,550
Dreher	Vienna	390,029
Empire	Milwaukee	347,410
Schlitz	"	319,837
Ehret	New York	311,337
St. Marc	Vienna	290,480
Löwenbrau	Munich	337,739
Bergner & Engel	Philadelphia	241,143
Pachorr	Munich	228,366
Liesing	Vienna	251,739

The Anheuser-Busch Brewing Company of St. Louis, Missouri, is the largest brewery in the world. Its production in 1888 was 510,313 barrels, in 1889, 600,000, and in 1890, 700,000. It enlarged its capacity in 1891 and is now (1892) producing 6,000 barrels a day. The business employs some 2,500 men, consumes about 3,000,000 bushels of barley, nearly 2,250,000 pounds of hops, and 600,000,000 gallons of water. The Association bottled in

1888, 27,000,000 bottles of beer. A large bottle factory at Belleville, Illinois, is kept at work all the time making bottles for this concern. Its establishment at St. Louis covers over 400 acres. The piping of the brewery is more than 100 miles in length. The present annual capacity of the house is more than 800,000 barrels.

The method of Pasteur for sterilizing germs is adopted by the association for their export beer, and the product of the brewery has now gained a certain footing, not only on German ships sailing from New York, but in Germany itself. The total annual exports exceed 5,000,000 bottles.

As our country is entitled to the credit of having the largest brewery in the world, it is only fair to add that she owes it almost entirely to the energy and ability of the President of the Anheuser-Busch Association, Adolphus Busch.

The French are working hard at brewing and have made beer a fashionable drink, but up to the present time their production leaves much to be desired in the way of quality. It is probable, however, that it is only a question of a few years when they will make as good beer as anybody in the world. *Charles McK. Leoser.*

WORMS. The frequency of infection by worms in villages is strikingly shown in the following report of Grusdieff, though the relative frequency of the fish and pork tape-worms would be reversed with us. The fact is, the fish tape-worm is not encountered at all in this country.

Grusdieff examined the stools of two hundred and sixty children at a school in Kostroma, a village in Russia. The children varied in age from nine to eighteen years. The examination was microscopic. Of the two hundred and sixty cases examined, one hundred and forty-one, that is fifty-four per cent., were free of worms. The other cases showed one variety of worms, sometimes two, once three, as follows: Round-worm, eighty-six times; fish tape-worm, forty-four times; whip-worm, six times; thread-worm, six times; pork tape-worm, once.

Protozoa.—Cohen found in the stools of a previously healthy four-year-old child, treated at the Polyclinic in Gratz for fever and diarrhœa, besides the eggs of intestinal worms, white blood-corpuscles, and epithelium, cellular elements of active amœboid movement, mostly embodied in particles of mucus. They coincided morphologically with the amœbæ of dysentery described by Kartulis and Locsh, save that they were smaller, being but two or three times the diameter of the red blood-corpuscles. The author had previously reported the case of a six-months-old child likewise affected, in whose stools were found protozoa, of pear-shape, with pointed ends and a long swinging lash, and with a distinctly circumscribed nucleus at the end. These monadines disappeared from the stools after the use of a sublimate injection, and the colic and diarrhœa ceased.

Filaria.—Matas has reported a case of filaria sanguinis hominis in New Orleans. A cigar-maker, aged nineteen, suffered with dropsy in the right tunica vaginalis testis, which was ascertained to be chylous. A microscopic examination showed the presence of embryos of the filaria, a parasite hitherto unknown in that region. The filaria itself was not found, on making the radical operation. The tunica was of natural thickness, the testicle perfectly healthy. The blood of the patient contained, as usual, only at night, numerous embryos.

Whip-worm.—Mossbrugger has described a case of infection by the whip-worm in myriads, producing an intense anæmia, uninfluenced by any kind of therapy. The author believed that the whip-worm was not, therefore, always such an innocent parasite.

Trichinosis.—Fränkel ascribes the frequency of trichinosis in Germany, not to the importation of infected American meat, but to the ingestion of domestic meat, raw, or uncooked. The inspection of meat for trichina is expensive and unsatisfactory because of its imperfectness.

Lewin finds the changes in the muscles in trichinosis to be exclusively a parenchymatous myositis with tendency to degeneration. In the myositis of anthrax the process begins and remains confined mostly to the connective tissue, the perimysium internum, while in the myositis of trichinosis the perimysium is unaffected and the true muscular element is the seat of the pathological process. A more decided example of the dependence of the form of inflammation upon the cause of the inflammation could scarcely be imagined.

Distoma.—Raillet finds that the distoma hepaticum is not nourished by bile, as Küchenmeister supposed, but by blood. The arterial system of a sheep, which suffered distomatosis, was injected with a solution of gyps, 500.0; ultramarine blue, 45.0; water, 1,000.0. The specimens of distoma in the bowel discharges of the sheep were, in the majority of cases, colored blue in consequence of the absorption from the blood.

Tape-worm.—Courmount and Bataillon, zoölogical prosectors at Lyons, showed to the Lyons Medical Society a tape-worm which they had found living in the peritoneal sac of a chimpanzee which had died of peritonitis and diarrhœa. The worm was found in the vicinity of a perforation of the stomach, and was supposed to have wandered from the intestine.

Pernicious Anæmia from Tape-worm.—Szimanski reported a case of anæmia which he considered pernicious, and for which he had made a fatal prognosis. The accidental discharge of segments led to the treatment of tape-worm, and secured the evacuation, under severe pain, of four worms with heads. All the bad symptoms disappeared in a short time. The patient shortly afterward became pregnant, and was delivered of a healthy child.

Pálmai reported a case of a woman, aged twenty, affected for ten years with tape-worm diarrhœa, neurasthenia, *anæmia* of high degree, terrible dysmenorrhœa; sterile, though married for three years. A dose of fresh male fern brought away a tape-worm in toto, 3½ m. in length. The patient's condition improved in the course of the next few days; all the subjective signs yielded, the menses returned, the woman became pregnant, and the dysmenorrhœa subsequently disappeared.

Cysticerci.—Laboulbene describes a method of making muscle cysticerci visible in slaughtered animals. They shrink usually on contact with air and become almost invisible. The cysts appear in the form of white spots, and show their original characteristic form under the application of either water or glycerine. The recognition of the cysticercus is, therefore, easier than that of the trichina. The echinococcus multilocularis is, according to Ostertag, frequently observed in cattle, especially in the liver, but differs from the same disease in man in the fact that it shows no icterus, no cirrhosis. The author found but one case in two hundred thousand pigs. With Vierordt he considers it a special variety, and the coincidence of the multilocular with the unilocular echinococcus is, he says, an accident.

Echinococcus.—König reports a case of rupture of a liver echinococcus into the peritoneal sac. Certain cysts passed to the hypogastric region, where they commenced growth, and were removed by operation.

Chaintere demonstrated, by means of laminaria tents and rubber tubes, the presence of cysts in the spleen.

Halidford cured a case by incision and drainage. Subsequent cysts were cured by puncture and aspiration.

Archangelskaja reported a fluctuating tumor at the lower border of the left scapula, which consisted of hydatids, and was cured by incision.

Vierordt reports the occurrence of two cases of multilocular echinococcus in a boy and girl, at the ages of eight and eleven.

Herrmann reports four cases of echinococcus of the spleen, in which the diagnosis of the abdominal tumor was established by puncture.

Langenbuch, in his work on "Echinococcus of the Liver and its Surgery," with special reference to various operations, declares that puncture has the danger of peritonitis and of dispersing echinococcus germs. It is unreliable and not to be recommended as an accurate method, and is justifiable only for diagnostic purposes

before radical operation. Electro-puncture is likewise imperfect. The various medicated injections have only historic interest, except that of sublimate, which may have a future.

Naphthol, recommended by Chauffard, merits consideration. The multiple punctures of Jobert de Lamballes, with the capillary trocar, and the aspiration method of Dieulafoy, have been set aside for the method of puncture, subsequent drainage, and irrigation, which may be practised by the ordinary physician. This method forms a transition to the radical operation for the removal of the parasite after adhesion has been secured between the liver and the abdominal wall. This adhesion is accomplished by various caustics or by the insertion of two cannulæ, that an agglutination may take place between them. This is the principle of the double section, which has found wide advocacy. The chief merit of it lies in the prevention of scattering of echinococcus germs in the peritoneal sac. This dissemination may be prevented also by ligation, with sutures hermetically shutting off the peritoneal sac. This method, according to the author, gives the safest results. It may be done some time before the radical operation. More heroic procedures, resections, or extirpations, are attended with too great dangers for general adoption.

Total discharge of all the worms may be secured by the use of the knife, or the Paquelin cautery, with subsequent drainage. Subphrenic echinococcus may require displacement of the liver (Landau) to secure room for operation, or peripleural incision (Israel, Genzner), or extra-peritoneal lumbar section, according to the situation of the worm. Echinococci in the peritoneal sac are removed by irrigation, the patient lying upon the side, with elevated chest. Multiple worms may require numerous laparotomies and sublimate injections. This last procedure may be adopted in cases of multilocular echinococcus.

Maydl has reported a case of pleuritic exudation, due to echinococcus and metastases from the liver. Frequent recurrence necessitated repeated incisions and resections. During this time the patient expectorated echinococcus cysts mixed with blood. Final recovery.

ANTHELMINTICS.—Murovicz finds the following objections to the various anthelmintics: First, unreliability owing to the essential ethereal oil; second, secondary irritant effects on the intestinal canal; third, some agents, like santonin, may in strong doses induce general intoxication. *Naphthalin*, which the author recommends, is a safe means with prompt effect. Thread-worm and tape-worm, the last with heads, are voided after a single dose of fifteen grains of naphthalin. The dose is to be graduated, according to age, from five to fifteen grains. Castor-oil may follow the remedy in adults, and should preferably be administered with it in children.

Bronowski increased the value of the ethereal extract of *male fern* by the addition of a purgative and of *chloroform*. Chloroform benumbs the parasite and relaxes the hold of the hooks.

According to Poulson, the ethereal extract of male fern in the treatment of tape-worm has several times led to fatal poisoning. In other cases reported, death sometimes occurred in consequence of irritation of the stomach and intestines; at other times, in consequence of paralysis and affection of the central nervous system. Death occurs in consequence of general central paralysis. The inequality of the active principle in the extract is evidenced by the fact that, on one occasion, as small a quantity as four grammes produced very dangerous symptoms in an adult, while as much as twenty or thirty grammes has often been taken without danger. Of all the chemical constituents of the ethereal extract of male fern one only merits consideration: Filix acid. Its chemical composition, according to elementary analysis and molecular weight, is fixed at $C^{35}H^{42}O^{13}$. In this composition it is separated from a solution in alkalies by the addition of HCL, as an amorphous substance which is pharmacologically very active. The crystalline substance which is sometimes separated from the older ethereal extracts, and which has been called Filicin, is, from a pharmacological stand-point, perfectly ineffective, and is really an anhydride of Filix acid. Filix acid in the frog affects the central nervous system, which after a short period of excitement is entirely paralyzed; further, the heart, whose energy is markedly reduced. The pulse is diminished in both force and frequency. Innervation is disturbed in the automatic heart ganglia. The skeleton muscles of the frog lose the power of recovery after effort. In warm-blooded animals the paralysis of the heart occurs simultaneously with the general paralysis, which begins as an ascending spinal paralysis. Attacks of diarrhœa supervene, as in cases of poisoning by the extract in man. It is advisable, therefore, instead of using the extract, whose constituents vary, to employ the filix acid itself, as this acid is easily soluble in the intestinal canal, and is but little absorbable. Filix acid is soluble in oils, and is thus dissolved in the ethereal extract. It is advisable, also, instead of giving castor-oil at the same time for the purpose of removing the parasite, to use some other laxative, because the oil favors absorption. *James T. Whittaker.*

WOUND TREATMENT. The improvements which have been made in surgical technique during the last few years have transformed the province of surgery. Operations are daily performed with success which were not attempted two or three decades ago, or which were attended with so much danger as to make them unjustifiable.

Injuries which formerly were followed by death or amputation are now treated with little discomfort and without loss of life or limb. These truths come out with startling force if one compares the cases recorded in the "Surgical History of the War of the Rebellion" with the cases of to-day, and they are equally forceful when one reads our old hospital histories or the cases recorded by the older writers. Formerly the patients whose breasts were removed were under treatment for a period of from three to six months. Now, after the removal of the breast and axillary contents, patients are usually discharged from hospital care in about two weeks.

One of the older Bellevue Hospital surgeons once told me that at one time almost every case of compound fracture which was admitted to that hospital resulted fatally. At the present time, in this same hospital, compound fractures are regularly expected to do well, and many of them heal as well as simple ones.

Lindpainter reported at one time that eighty per cent. of all wounds in Nussbaum's clinic in Munich became infected with hospital gangrene; and also that erysipelas was so common that its appearance came to be considered as almost a normal occurrence. The suturing of wounds about the head was given up because the retained secretions favored erysipelas.

Healing by first intention was almost unknown. In one year, out of 17 amputations, 11 died of pyæmia alone.

A compound fracture was seldom to be observed in the division, since the limb was either amputated or soon became infected, and death followed from hospital gangrene or septicæmia.

The mortality after compound fractures, in Volkmann's clinic in Halle, during a long period of years, which embraced the administration of his predecessor and a part of his own, was forty per cent.

Compare these statements with Halsted's reports of the first 122 surgical cases treated in Johns Hopkins Hospital. Of 111 cases which were not suppurating when operated upon, 108 healed by primary union, 2 had suppuration, 1 had hemorrhage; of 11 cases which were actively suppurating at the time of operation, 8 healed primarily, 2 had some suppuration, 1 had active suppuration—122 cases, good and bad, and of these only 6 which did not heal by primary union.

At the present day hospital gangrene is almost unknown. Pyæmia is so uncommon that a man may well gain a large surgical experience without meeting more than a dozen cases. A suppurating wound is a reproach

to the surgeon or his assistants and leads to inquiry as to its cause.

It is evident that the modern changes in surgical technique are of vital importance, and that the surgeon is well repaid for a study of the principles which underlie them and the details which are necessary in carrying them out.

They have come because we have learned the causes of suppuration, and improvements in technique are all the time occurring as we learn more and more about these causes.

The introduction of antisepsis was a great stride in the advancement of surgery, but so many changes have been made since the carbolic spray and the Lister dressing were introduced that we may fairly say that we have advanced to yet another epoch in surgical progress.

We must recognize that there are two opposing forces in most cases where there are open wounds: 1. The developing form of the infectious agent. 2. The resisting form of the patient.

Bacteria which have the power of causing pus are present in the majority of surgical wounds. They exist in the patient's skin so deeply that they are not to be washed away, they are frequently present in the diseased tissue, they are far too often on the surgeon's hands and those of his assistants in spite of careful washing, and if they are not on the instruments or sponges at the beginning of an operation they are very likely to be there before its end owing to contact with some unsterilized object.

Bossowski studied the bacteria in fifty fresh wounds which were treated antiseptically. In forty of them he found bacteria: the staphyloccus aureus, nine times; the streptococcus pyogenes, two times; the staphylococcus albus, twenty-six times; and non-pyogenic bacteria, many times.

Kümmel found that pieces of muscle, adipose, or connective tissue taken from fresh wounds immediately after irrigation with a 1 to 10,000 sublimate solution, which had been continued throughout the entire operation, contained bacteria. The same result was obtained after a frequent washing with 1 to 1,000 sublimate solution.

There are many kinds of bacteria which are capable of causing pus production. The peculiarities of the suppuration differ with the different varieties of infection, and treatment must be modified accordingly. The tubercle bacilli, for instance, cause a slowly progressing suppuration which often results in the production of cold abscesses. A pint of this tubercular pus may exist in the system for weeks and cause very moderate constitutional symptoms.

The streptococcus pyogenes, on the other hand, is an infective agent of a very different nature. If a colony of these cocci get under the skin of the finger-tip, as, for instance, in a scratch which comes in contact with the fluid from a case of puerperal peritonitis, they may cause a septicæmia so virulent as to be fatal in a few days.

Or if somewhat less virulent they may start an inflammation which runs up the tendon sheaths and produces pus in many of the tissues of the hand and forearm, which involves the lymphatics and causes abscesses in the axilla or elsewhere. They are especially apt to cause spreading phlegmon, and are found either alone or in combination with other bacteria in numerous varieties of inflammation.

Moreover, they are so abundant and so generally disseminated that they must continually be guarded against.

In sixty-five cases of suppuration at the Vanderbilt Clinic, which were examined by Dr. Park and myself, streptococci were present in forty-eight. They were present in practically all of the severe inflammations.

The staphylococcus pyogenes aureus organisms are still more common; they are found in the majority of suppurating wounds, abscesses, boils, etc. They tend to form circumscribed abscesses rather than the spreading inflammation which is caused by the streptococci.

They are so generally disseminated that unprotected wounds may regularly be expected to become infected by them, and they may be so virulent as to cause fatal pyæmia or septicæmia.

Welch found them very frequently on the hands of surgeons and their assistants who had to do with suppurating cases of any kind; sometimes they were present several days after contact with surgical cases.

Prudden and Ullman found them frequently present in the air, and among the dust particles, especially in much-used rooms.

They do not die easily nor are they easily killed by freezing, and they grow readily under varied conditions.

Surgically speaking we have no right to expect any unsterilized object to be free from them.

The staphylococcus pyogenes albus is similar to the staphylococcus aureus in many respects, but seems to be far less virulent.

In the fresh wounds in which Bossowski found the streptococcus pyogenes and the staphylococcus aureus, there was regularly suppuration; but in those in which the staphylococcus albus was present alone there was either primary union or a very slight and almost harmless infection along the drainage-tube or the sutures. It is quite possible that the staphylococcus epidermis albus which Welch has described is identical with the staphylococcus pyogenes albus, which has frequently been found by other observers. This coccus is remarkably interesting in that it exists in the epidermis so deeply that it cannot be removed by ordinary disinfection. The skin seems to be its normal habitat. After thoroughly cleansing and disinfecting it, this white coccus may be obtained on a piece of sterilized thread by passing it through the deeper layers of the skin. Its infective power seems to be very weak. It is capable of producing small stitch-hole abscesses, or suppuration along the sides of a drainage-tube or superficial abscesses. But unless the tissues have very slight vitality it does not seem to be capable of producing serious inflammation. The bacillus coli communis is also capable of producing serious infection and suppuration. This bacillus lives normally in the large intestine. In cases of injury to the intestine it may get into the peritoneal cavity and cause fatal peritonitis. Welch reports several cases of peritonitis in which only this bacillus was found. It was found several times in pure culture in aseptically treated laparotomy wounds. It was generally accompanied with moderate fever and a thin, brownish, slightly purulent discharge, and the smooth and rapid healing of the wound was interfered with.

Numerous other bacteria may be concerned in pus production: The diplococcus pneumoniæ of Fränkel and Weichselbaum, the typhoid bacillus, the staphylococcus pyocyaneus, gonococcus, bacillus pyogenes fetidus, proteus zenzeri, and micrococcus tetragenus may be mentioned among these.

The same species of bacteria differ greatly under different surroundings. In certain abscesses they seem to exhaust themselves, and the pus becomes strictly sterile. Numerous cases of this kind have been reported. On the other hand, under certain conditions they seem capable of showing increased resistance to germicides.

Trambusti made cultures of various micro-organisms, and then transferred them into bouillon, in which he put increasing quantities of sublimate. He found that the bacteria in this way gained a tolerance of antiseptics. For example, Friedländer's pneumococci could be put into a 1 to 2,000 solution of sublimate in bouillon without the prevention of their growth, while the growth of the same bacteria without such treatment was checked in a 1 to 15,000 solution of sublimate in bouillon. The pathogenic action of the bacteria also differed. Some retained their pathogenic qualities as long as they retained the power of growth; others lost it much earlier. It should be remembered that in this experiment a certain part of the sublimate probably was exhausted by chemical combination with the elements of the beef-tea.

In order to test this matter of varying virulence Welch injected into the ear veins of rabbits bouillon cultures, forty-eight hours old, of the staphylococcus aureus obtained from many different sources. "Considerable

variatious in virulence were found to exist both in the original cultures and in the successive generations of the same culture. The most virulent culture was one from a beginning furuncle. The injection of 0.1 c.c. of this culture caused the death of the rabbit in twenty-four hours, with a large number of staphylococci in the blood and many necrotic foci in the kidneys. After the second generation the virulence was lessened. On the other hand, he injected into the ear veins of rabbits 1.5 c.c. of a similar bouillon culture of staphylococcus pyogenes aureus, which came from a cirrhotic liver, without any apparent effect, the animals being still alive eight months after the injection.

"These extremes are met only occasionally. In a great majority of cases we have found the injection of 0.2 to 0.3 c.c. of bouillon cultures sufficient to kill the animal in four to seven days, with abscesses in the kidneys and heart, and occasionally elsewhere. As a rule, there was no material change in the degree of virulence for many successive generations; but sometimes, without any apparent cause, there would occur a marked weakening of the virulence, either after a few generations or after many."

It is possible that accompanying toxic substances may have an influence on these variations. This question of the varying virulence of different bacteria, and of the same species of bacteria under varying circumstances, is of very great importance to the surgeon. How frequently do we hear men say that it is unnecessary to treat a wound or abscess antiseptically, because it is already infected! Such men forget that there are different grades of infection, and that we may do a patient a very great injury by permitting a mild infection to become changed into a virulent one. A surgeon who introduces streptococci or the yellow staphylococci into a tubercular abscess has done his patient an injury which may have the most disastrous results. If an abscess from hip-joint disease has burrowed into the thigh it may be far better to leave it unopened, in the hope that the joint may become shut off from the abscess, than to open it and make an avenue for general infection, which will not be easily managed in this locality.

If an abscess is caused by the staphylococcus epidermis albus, it is plainly wise to keep out the yellow staphylococcus and the streptococcus pyogenes, because they are much more virulent than the white coccus.

In the opening of an abscess which contains sterile pus one should use as much care as in the making of a fresh wound.

Inasmuch as we cannot clinically determine all of these conditions, it is plainly a surgical duty to regard all unsterilized objects as septic and all infected wounds as capable of receiving worse infection.

The inflammation which takes place about a suppurating wound is a barrier against further infection, but in spite of this an abscess or infected wound may frequently be made far worse by the introduction of new sepsis.

We have personally traced this process by making cultures from the pus in wounds during various stages of suppuration, and have found that the symptoms vary when new infection has occurred. Moreover, we must endeavor to keep out all infection, and not to be misled by moderately good results. If a laparotomist saves the peritoneal cavity and yet has abscesses in the abdominal wall, it shows that there has been an error in technique, and that the peritoneum has escaped either through chance or because it has been able to overcome the bacteria. If a surgeon has frequently a slight form of suppuration in his wounds, it shows that there is an avenue of infection somewhere, and that if a virulent infection happens to find the avenue, he may lose his patient.

On the other hand, the system of the patient is able to successfully cope with a limited number of pyogenic bacteria and to prevent their growth. Cheyne estimates that several thousand may be present in a wound without causing suppuration.

Nearly all surgeons have met with cases in which infected material has come in contact with a fresh wound, and still the wound has healed kindly.

Grawitz found that he could inject 5 to 10 c.c. of the suspension of the yellow staphylococcus in salt solution into the abdominal cavity of rabbits and dogs without producing any perceptible effect. These cocci, however, are capable of producing suppuration in these animals, as a fraction of a drop of a similar suspension, when injected into the rabbit's eye, will set up a suppurative inflammation. A larger amount will produce an abscess in the loose subcutaneous tissue of the back. These experiments have been verified by numerous observers. Waterhouse injected under the skin of the human abdomen and of the scrotum 0.25 c.c. of a suspension of staphylococcus aureus made from mixing one loopful from an agar culture with 5 c.c. of water, and the result was completely negative.

This same power of the system to overcome infection is shown in medical diseases. Tubercle bacilli are found encapsulated and shut away in the bronchial lymph-nodes. The Klebs-Loeffler bacillus causes a false membrane and very slight constitutional symptoms in one person, while in a patient infected from this person it may cause profound constitutional symptoms and death.

In considering, then, the problems of wound treatment, we must ever bear these two forces in mind: the growing power of the bacteria, the resisting power of the patient. We should keep out infective agents. We should avoid injuring tissues and so impairing their vitality and power to overcome any bacteria which may gain entrance. The first is more difficult, and the second more important, than was formerly supposed. A few years ago men satisfied their surgical consciences by washing their hands in soap and water with more or less care, and then dipping them in a 1 to 1,000 bichloride solution, immersing their instruments in a five per cent. solution of carbolic acid, and sponging and irrigating the cut tissues with 1 to 1,000 bichloride solution.

This method, however, did not keep out the bacteria, and it did unnecessarily injure the tissues; hence it was defective in both respects. The present methods aim at a technique which will exclude bacteria more effectively and injure the tissues less.

GERMICIDES.—Before studying the details of this technique we should arrive at an understanding of the values of various germicidal agents. The blind faith which has been put in the germicidal power of solutions of corrosive sublimate and carbolic acid is startling. We were told years ago that a short immersion in these fluids killed bacteria, and so generally has this belief been accepted that towels, cotton pledgets, instruments, dressings, and even the hands of the operator, have been supposed to be aseptic after an immersion of a few seconds or a few minutes. Recent studies have shown many fallacies in this belief.

The original experiments, which were made with solutions of bichloride of mercury, were so conducted that a small residue of the bichloride was transferred to the nutrient media in which the bacteria were planted. This small quantity has been found sufficient to inhibit bacterial growth.

Geppert, after saturating threads with anthrax spores, and immersing them in a 1 to 1,000 corrosive sublimate solution for varying lengths of time, precipitated the adherent sublimate with ammonium sulphide, and then placed the threads in culture media. He found that after one, two, and three hours in sublimate solution a few spores retained their power of growth, and in one exceptional case he obtained a growth beside a knot in the thread after twenty-four hours' immersion. Behring obtained growths from anthrax spores which had been immersed in 1 to 1,000 sublimate solution for ten hours. Nissen found that anthrax spores could live after a four hours' immersion in one per cent. corrosive sublimate solution. Abbot repeated Geppert's experiments and obtained similar results. He also found that staphylococcus pyogenes aureus would grow after a one hour's stay in 1 to 1,000 solution of sublimate in nutrient bouillon, or after twenty minutes' exposure in a 1 to 1,000 watery solution of sublimate.

The writer has collected pus in small amount on cotton pledgets which were saturated with 1 to 1,500 corro-

sive sublimate solution, and two and a half hours later he has touched nutrient agar with them and obtained abundant growth of streptococcus pyogenes. He has also repeatedly touched swabs to wounds which had just been thoroughly irrigated with 1 to 1,000 sublimate solution, and has obtained abundant growth of streptococci and staphylococci pyogenes aurei from the swabs.

There are numerous considerations which should influence the use of germicides. It is believed that sublimate solutions kill bacteria by a chemical action which takes place between the sublimate and the bacteria. If the number of bacteria is very great, and the amount of sublimate is small, it is evident that the chemical power of the sublimate may be exhausted before the bacteria are all killed. Abbot found that large quantities of bacteria were not killed in a solution which was strong enough to destroy small quantities. Similarly, any albuminous substance which forms a chemical compound with the sublimate leaves far less sublimate to act on the bacteria. Abbot found that a 1 to 1,000 watery solution of sublimate had a far greater germicidal power than a 1 to 1,000 nutrient bouillon solution.

In a similar way, solutions of sublimate which have stood for a considerable time may have lost their power. Abbot found a marked difference between the germicidal power of a fresh sublimate solution and one that had stood for four days.

Temperature, again, exerts a great influence. Heider found that a five per cent. solution of carbolic acid, at a temperature of 75° C., killed anthrax spores in fifteen minutes, whereas a similar solution did not kill them in thirty-six days at the ordinary room temperature. Behring found that staphylococci pyogenes aurei, when exposed to a 1 to 1,000 corrosive sublimate solution at a temperature of 3° C., were not killed in one hour. At a temperature of 22° C. they were not killed in twenty-five minutes, whereas at a temperature of 36° C. they were killed in five minutes. He also found that anthrax spores were killed in thirty to sixty minutes at 70° C., and in eight to ten minutes at 85° C., when immersed in a one and four-tenths per cent. aqueous solution of sodium carbonate.

It is of vast importance in the consideration of germicides to remember that certain substances may protect the bacteria from chemical action. Oil and grease are the most marked instances of this, but pus, blood, and dirt may have a decided protective influence. Koch reported, more than ten years ago, that oil prevented the action of germicides. Silk threads which are impregnated with pus bacteria and then dipped in oil may lie for days, and even for weeks, in an aqueous 1 to 2,000 corrosive sublimate solution without the killing of the bacteria. Blood, pus, sputum, etc., may in a similar way protect bacteria from chemical action.

Furthermore, different bacteria of the same species seem to have a very different tolerance of germicides. This has already been referred to in the paragraphs on bacteria. Esmarch, in studying the subject, found that some anthrax spores were killed by steam in one minute, whereas an exposure of twelve minutes was necessary to kill others.

In consideration of all these possible sources of error it is evident that we cannot blindly trust to the quick action of chemical sterilization. A one per cent. solution of bichloride of mercury may sterilize an object in a few minutes, but if there is grease, oil, mucus, blood, or pus upon it the object may still be septic after an immersion of an hour, or even of many hours. Furthermore, what we suppose to be an efficient solution of sublimate may be almost useless, owing to the combination of the sublimate with albuminous material, soap, minerals in the water, etc. The weakening of the sublimate solution by the presence of other minerals in the water may be avoided by adding table salt to the solution.

The considerations which apply to sublimate solutions apply also to other chemical solutions. It is always to be remembered that the germicidal power of a five per cent. carbolic acid solution is far less than that of a one per cent. solution of corrosive sublimate. Heider, Geppert, Reidel, Fränkel, and many other observers record the survival of anthrax spores after an immersion in five per cent. solution of carbolic acid for days.

The appended table shows the germicidal power of a few heated liquids, with the authorities for the same:

Germicidal agent.	Temperature at which it was used.	Kind of micro-organism.	Length of exposure necessary for killing the micro-organisms.*	Observer.
Boiling water.	100° C.	Anthrax spores.	2 minutes.	Geppert, Berl. klin. Woch., 1890, p. 246.
				Schimmelbusch, Arch. f. klin. Chir., xlii.
Boiling water.	100° C.	Bacilli and cocci.	2 to 5 seconds.	Ibid.
Boiling water.	100° C.	Staphylococcus pyogenes aureus; bacillus pyocyaneus.	2 to 3 seconds.	Ibid.
Boiling one per cent. aqueous solution of sodium carbonate.	100° C.	Anthrax spores.	2 minutes.	Ibid.
Boiling one per cent. aqueous solution of sodium carbonate.	100° C.	Pus; staphylococcus pyogenes aureus; bacillus pyocyaneus.	2 to 3 seconds.	Ibid.
One and four-tenths per cent. aqueous solution of sodium carbonate.	85° C.	Anthrax spores.	8 to 10 minutes.	Behring, Zeitsch. f. Hygiene, 1890, p. 451.
One and four-tenths per cent. aqueous solution of sodium carbonate.	80° to 83° C.	Anthrax spores.	10 minutes.	Ibid.
One and four-tenths per cent. aqueous solution of sodium carbonate.	77° C.	Anthrax spores.	15 minutes.	Ibid.
One and four-tenths per cent. aqueous solution of sodium carbonate.	75° C.	Anthrax spores.	20 minutes.	Ibid.
One and four-tenths per cent. aqueous solution of sodium carbonate.	70° C.	Anthrax spores.	30 to 60 minutes.	Ibid.
Five per cent. solution of carbolic acid.	Ordinary room-temperature.	Anthrax spores.	Not killed in 36 days.	Heider, Centralblatt f. Bakt. und Parasitk., Bd. ix., p. 221.
Five per cent. solution of carbolic acid.	55° C.	Anthrax spores.	30 minutes.	Ibid.
Five per cent. solution of carbolic acid.	75° C.	Anthrax spores.	15 minutes.	Ibid.
Blood.	55° C.	Anthrax bacilli.	10 minutes.	Toussaint, quoted by Fränkel, Grundriss Bact'kunde, p. 257
Weak alkaline bouillon.	54° C.	Koch's comma bacillus (cholera).	3 minutes.	Van Geun's Arch. f. Hygiene, 1889, p. 402.
Weak alkaline bouillon.	56° C.	Bacillus of typhoid fever.	3 minutes.	Ibid.
Weak alkaline bouillon.	60° C.	Bacillus of septicæmia of mice.	Few seconds.	Ibid.
Weak alkaline bouillon.	78° C.	Bacillus of malignant œdema.	Few seconds.	Ibid.
Weak alkaline bouillon.	80° C.	Pneumococcus of Friedländer.	1 minute.	Ibid.
Weak alkaline bouillon.	70° C.	Tubercle bacilli.	10 minutes.	Yersin, Annales de l'Inst. Pasteur, t. i., No. 2.
Milk.	68° to 69° C.	Tubercle bacilli.	30 minutes.	Bitter, Zeitsch. f. Hygiene, 1890, p. 255.

* The times given are not absolute, because in some cases the organisms were exposed to a certain varying heat while the medium was being heated and was cooling.

Heat is to be used wherever it can be in sterilization. Boiling fluids have very great germicidal power. According to Geppert and Schimmelbusch, boiling water kills anthrax spores in two minutes. The latter observer states that the vegetative forms of the bacilli and the cocci are killed by it in from one to five seconds. Steam is less powerful; it kills anthrax spores in from five to twelve minutes (Esmarch). Under pressure its temperature may be raised and its efficacy somewhat increased.

Dry heat is considerably less powerful. Sporeless bacteria are killed in air at a temperature of 212° F. in an hour and a half (Koch and Wolfhügel); while spores must be exposed to a temperature of 140° F. for three hours to insure their destruction.

Heated liquids furnish us another method of using heat in disinfecting. It sometimes happens that boiling liquids will injure materials which may be thoroughly sterilized by liquids which are heated to 160° and 175° F. Freeman has thoroughly studied this subject, and applied it to the preparation of milk by a method called Pasteurization. His method consists in putting the bottles of milk into a measured quantity of boiling water and allowing them to remain there as the water cools. This raises the milk to a temperature of about 167° F., and holds it there for about twenty minutes. This temperature he found sufficient to sterilize milk which held 8,000 to 230,000 bacteria to each c.c. Van Gueno found a similar or even a lower temperature sufficient to kill, in times varying from ten minutes to a few seconds, Koch's comma bacillus, the bacillus of septicæmia of mice, and the tubercle bacillus, when in suspension in weak alkaline bouillon. The bacillus of malignant œdema was killed in a few seconds at 173° F., and the pneumococcus of Friedländer was killed in one minute at 176° F. Behring found that anthrax spores were killed in $1\frac{1}{10}$ per cent. aqueous solution of sodium carbonate, at temperatures from 167° to 185° F., in from eight to twenty minutes.

Bearing these points in mind, it is evident that heat should be used for surgical disinfection whenever it is possible. Boiling alkaline solutions overcome almost entirely the objections which are raised to cold chemical solutions. And where boiling solutions or steam cannot be used, we can still, in most instances, heat the solutions, and thus increase their germicidal action.

In coming to the consideration of surgical technique proper, our subject may fairly include all those details which are essential to the exclusion of bacteria, and the keeping of the tissues in the best condition possible, for upon these details depends surgical success. The limitations of this article, however, forbid the exhaustive study of all details.

Our subject naturally divides itself into three parts: 1. Preparation for the operation. 2. The operation itself. 3. After-treatment.

Under the first, we may consider preparations of the surgeon, his assistants, the patient, the room, the table, towels, instruments, dressings, ligatures, sutures, sponges or absorbent pads, solutions, and dishes.

Under the second we may consider the methods of avoiding contact between sterilized and unsterilized objects, the management of dead spaces, healing under blood-clot, draining, irrigation, and the injury to tissues.

Under the third we may consider after-dressing and certain principles of medication.

I. Preparation for the Operation.

Preparation of Surgeon and Assistants.—It is believed to be wise for the surgeon and his assistants to avoid contact with septic cases and with contagious diseases so far as is possible, and to preserve the strictest personal cleanliness. This is of especial importance on the day of the operation; if septic cases must be cared for during the day they should not be visited until after the operation. If septic and clean cases are both to be operated upon, the clean cases should be attended to first.

Before operation a freshly washed, short-sleeved gown or duck suit which fits closely about the neck and extends to the ankles, should be put on. A damp sterilized towel may be pinned across the chest like an apron. The sterilizing of the hands is one of the most difficult of procedures. All surgeons' hands become infected again and again, each contact with pus or any unclean matter leaving its residue of infection. We may state positively that simple washing in soap and water will not sterilize infected hands. At the Johns Hopkins Hospital bacterial cultures were made from the subungual spaces of physicians who believed they could thus clean their hands, and cocci were regularly found to be present after the washing. Welch found the staphylococcus pyogenes aureus very frequently on the hands of surgeons and their assistants who had to do with suppurating cases of any kind. It was found several days after any contact with surgical cases. It was only exceptionally found on the hands of other persons.

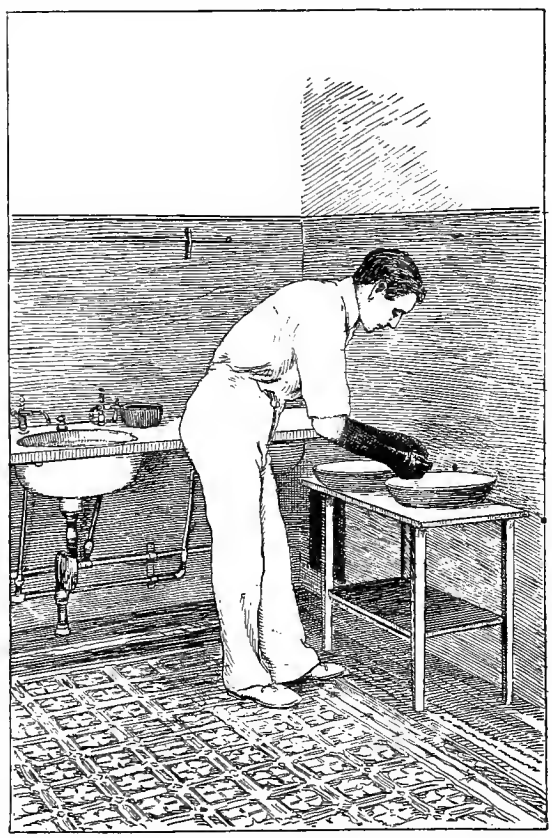

Fig. 681.—The Assistant in the concluding Steps of Sterilizing his Hands and Forearms, preparatory to Operation. The hands and arms are seen stained a deep mahogany color by saturated solution of permanganate of potash. (Kelly.)

Fürbringer's method of cleaning the hands is as follows: The nails should be kept trimmed short; the hands are to be scrubbed with brush and soap in hot water for one minute, especial attention being paid to the subungual spaces, which then are to be scraped carefully with a nail cleaner; then the hands are to be immersed for another minute in strong alcohol, and afterward in a 1 to 1,000 solution of corrosive sublimate for a minute.

This method is fairly efficient, but Geppert found that, after all, the bacteria on the hands were not entirely destroyed in that way, but that if the adherent sublimate was precipitated by the ammonium sulphide they would still grow. His observations have been verified at the Johns Hopkins Hospital, where the following method has been developed:

1. The nails are kept short and clean.

2. The hands are washed thoroughly for ten minutes with soap and water, the water being as hot as can be comfortably borne, and being frequently changed. A brush, sterilized by steam, is used, and any excess of soap is washed off with water.

3. The hands are immersed for from one to two minutes in a warm saturated solution of permanganate of potash.

4. They are then placed in a warm saturated solution of oxalic acid, where they remain until complete decolorization of the permanganate occurs.

5. They are next washed off with sterilized salt solution or water.

6. They are then immersed for ten minutes in sublimate solution, 1 to 1,500.

The bacteriological examination of the skin thus treated, even after the mercury has been precipitated, yields al-

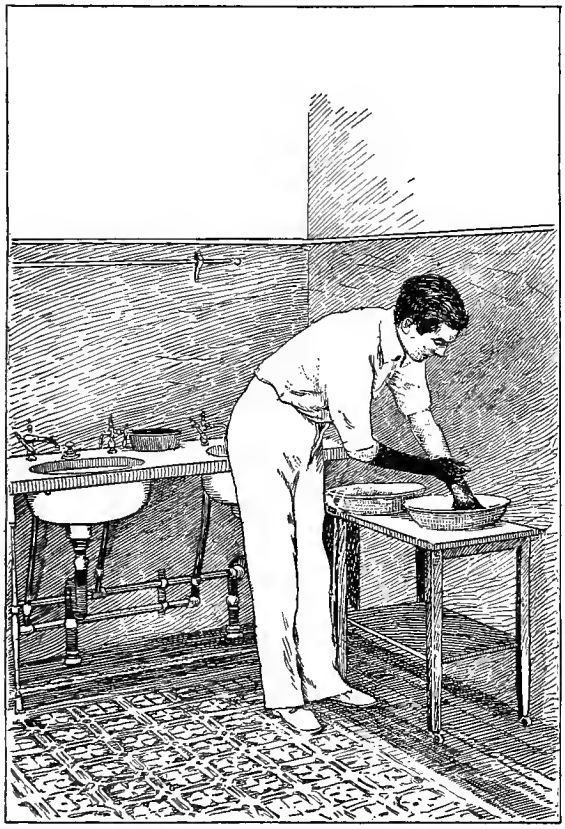

FIG. 682.—The Final Step in this Method of Disinfection, the Removal of the Permanganate Stain by Oxalic Acid. The decolorization of the left arm is seen. (Kelly.)

most uniformly negative results, the material for the cultures being taken from underneath and around the nails.

Threads which are impregnated with bacteria are not sterilized by this procedure. A great objection to the method is that it irritates the skin so much as to frequently cause a dermatitis. Some men cannot use it at all, and hardly anyone can use it frequently. We advise its use by those who do not get a dermatitis thereby, and Fürbringer's method by those who do.

One point has been much overlooked in the case of the hands, viz., the keeping of the skin itself in a healthy condition. Healthy skin may harbor thousands of bacteria, but inflamed skin harbors them by the million. Again, skin which is cracked and furrowed by the use of strong antiseptics offers innumerable crevices for the lodgement and protection of bacteria.

Hang-nails and little cuts or scratches should be immediately protected. They may be well cared for by covering them with a bit of gauze, wet in sublimate solution, and then slipping on a rubber finger-cover. If one must operate with a defect of this kind on the hand, he should either wear a rubber glove or a rubber finger-cover which has been efficiently sterilized in sublimate solution. A finger-ring should never be worn during an operation. The nails should always be kept short.

The hair or beard may carry infection. I have frequently seen men with loose dry hair touch heads directly over an open wound, and nurses with wavy unprotected hair working about in such a way as to give much danger of infection from falling dandruff or dust. The hair should be so dressed that dandruff cannot fall, or else the head should be covered.

The nurses and assistants should be as careful as the operator in all dress details.

The preparation of the patient involves two lines of procedure: 1. The cleansing of the skin or mucous membrane at the site of the operation. 2. The constitutional treatment.

The first of these is of very great importance. Nearly twenty years ago Eberth described numerous bacteria in the normal perspiration, and since that time numerous observers have described bacteria on the skin and hair. The uniform temperature, the moisture, and the desquamating epithelium give the conditions favorable for bacterial growth. They are particularly abundant in the axilla, the anal furrow, and the interdigital space. The staphylococcus epidermis albus of Welch has been already referred to. We may expect it to be regularly present in the skin, and must remember that it is capable of setting up a suppuration which is more or less virulent according to circumstances. Lockwood stained sections of skin of two breasts which had been carefully cleaned, and found bacilli and cocci in the epidermis and hair-follicles. They were probably living when the skin was removed, for another bit of similarly-prepared skin, dropped into bouillon, yielded a free growth of streptococci, diplococci, and bacilli. After surface disinfection the contents of the sebaceous glands yielded cocci and bacilli, as did also the sweat-glands.

More than one large book has been written about the micro-organisms found in the mouth. Winter states that in one-half of all cases the female genital canal contains pathogenic organisms in a condition for virulent growth. Gönure and many other writers describe them in much detail. The male urethra also contains them, as do the secretions from the nose and conjunctiva.

The proper preparation of the site of operation is therefore a difficult problem, and of very great importance. The most satisfactory proceeding which I know of is the following: When the incision is to be made through the skin, frequent warm baths should be taken before the operation, and the night before it any hair which grows about the site of operation should be shaved. A poultice made of mild soft soap should then be applied and left on overnight. After this a large amount of dead epithelium comes off by gentle rubbing. A piece of gauze may then be put on moistened in a solution, alum sulphate, 1 part; acetate of lead, 5 parts; water, 200 parts. After the patient is on the operating-table the part should be again scrubbed with soap and water by a person whose hands are aseptic, the soap, water, and hand-brush having all been previously sterilized, The skin may then be washed off with a solution of corrosive sublimate, 1 to 2,000. These procedures do not cause a dermatitis. Any procedure which does should be avoided.

If the operation is within the vagina, a warm douche of three per cent. boric acid solution, or one per cent. solution of carbolic acid, should be given twice daily for several days before the operation, and after the patient is on the table the vagina should be thoroughly scrubbed out with warm soap-suds, and douched with one per cent. carbolic solution, or bichloride solution 1 to 3,000.

In preparing for operations within the mouth, a peroxide of hydrogen mouth-wash (seven volumes) should be used for several days. In patients who have thus been treated I have found that, after removal of parts of the

upper and lower jaws, a packing of iodoform gauze would remain in the mouth for six days without becoming fetid; a mouth-wash being also used after the operation.

The *constitutional treatment* of the patient is to be conducted on the general principles of medicine. The bowels should be evacuated before operation. The stomach should be empty before the ether is administered. A syphilitic condition should be treated vigorously. Diabetes contraindicates any serious operation, unless without it the disease or injury is likely to terminate fatally.

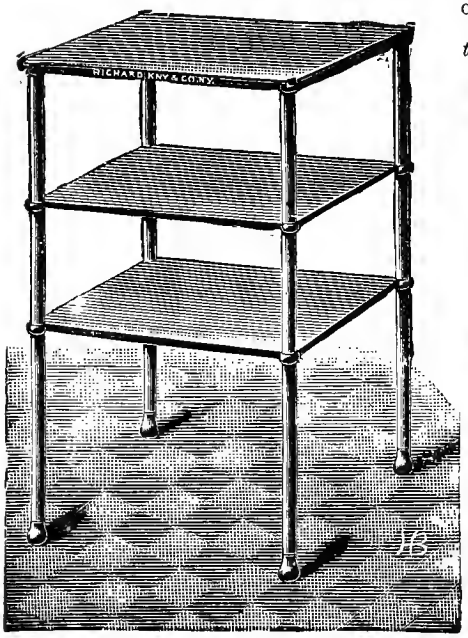

FIG. 683.—Stand Made of Iron and Glass for Holding Surgical Dressings.

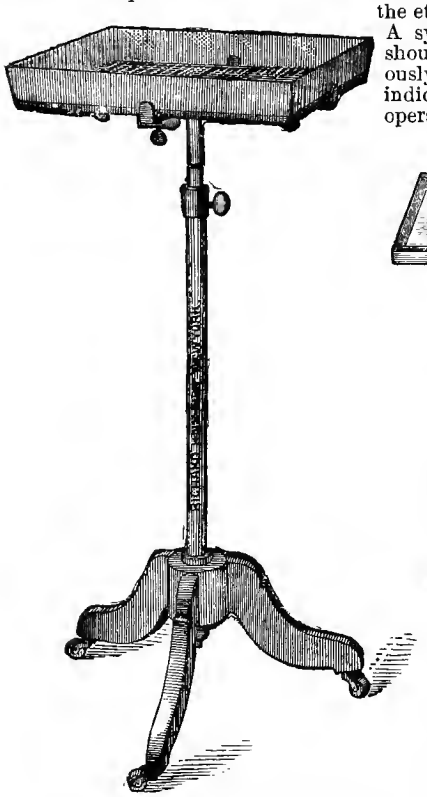

FIG. 684.—Stand for Holding Glass Instrument Tray.

The room should be large enough for the patient, the surgeon, and the assistants. It should have good light; it should be reasonably clean, and should be free from dust. There is no danger from air-infection unless particles of dust fall on the wound, or on something which will come in contact with it. It is not wise to sweep or dust a room just before an operation. This fills the air with dust particles which are capable of carrying infection. It is far better to close it for a few hours before the operation, and then, if the floor is carpeted, to cover it with something which will prevent the undue raising of dust. Stern found that after stirring up the dust in a room and then closing it, nearly all the dust settled to the floor in one and a half hour, although the more attenuated particles, such as those which came from woollen and rags, and the mould spores, were somewhat slower in settling. The pieces of furniture or tables with which the operator or assistants come in contact should be covered with sterile sheets or towels. In regular operating-rooms, stands for dressings and instruments may well be made of metal or glass (Figs. 683 and 684). If, however, such stands have deep cracks between the glass and the metal they are really harder to clean than wooden ones are.

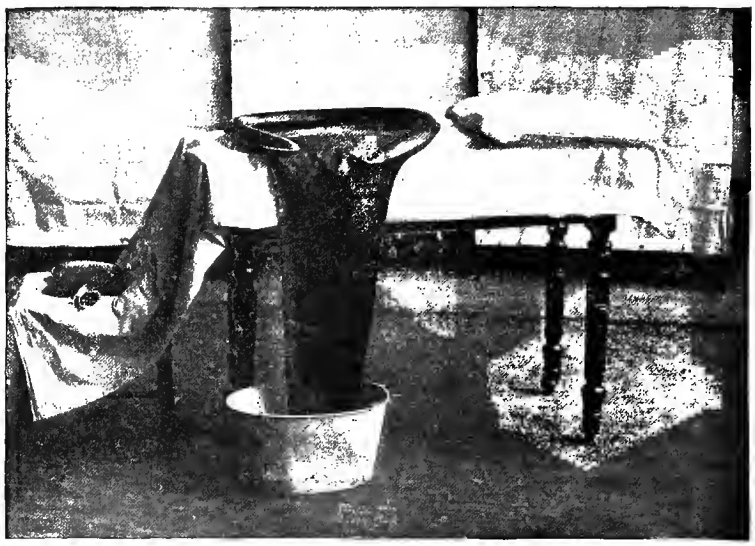

FIG. 685.—An Efficient Operating-table such as may be easily Prepared in any House. The patient's feet may rest on the warm-water bag which is on the chair. The Kelly pad is unnecessary if irrigation is not to be used.

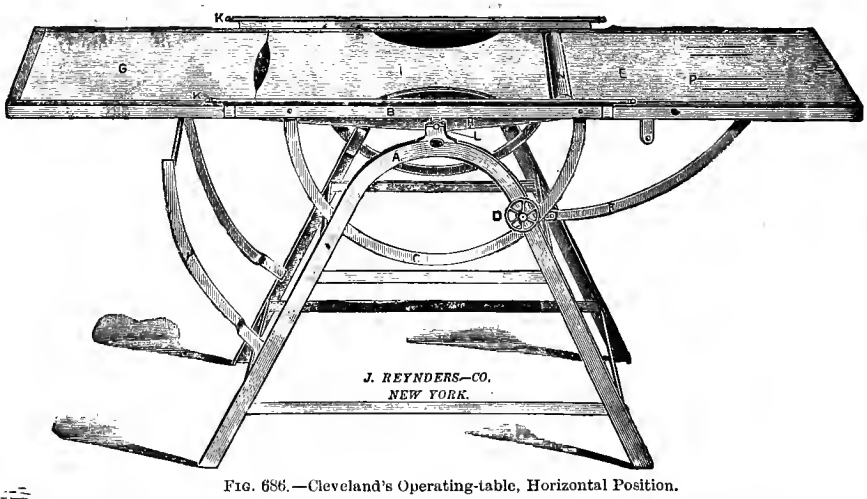

FIG. 686.—Cleveland's Operating-table, Horizontal Position.

The operating-table may be a plain kitchen-table, and still be efficient.

It should be 2 to 2½ feet wide. A length of four feet is sufficient if the patient's feet are placed on a rest at the foot of the table, or if the patient has to be placed in the lithotomy posture. It should be longer if the feet are to be extended on the table. If the operation is on the hand or arm, a small side-table should be used, or a leaf may be provided for the regular table.

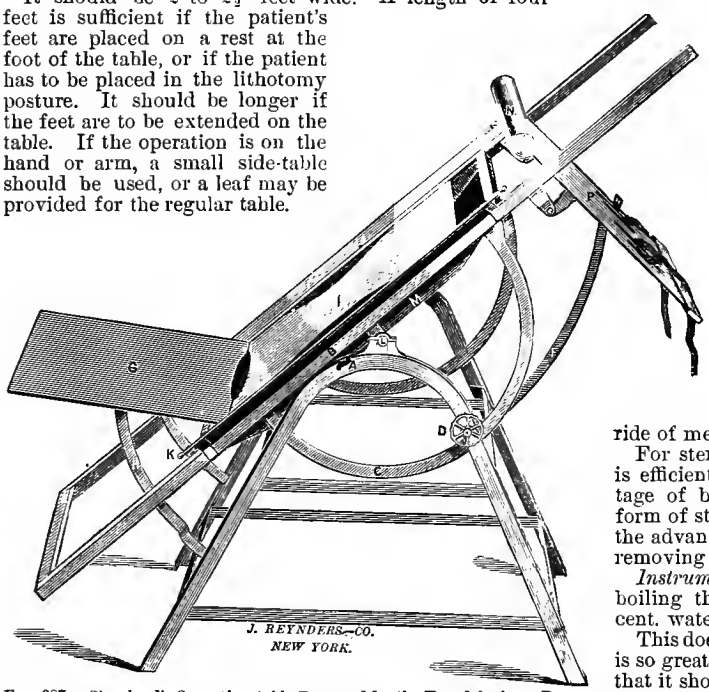

FIG. 687.—Cleveland's Operating-table Prepared for the Trendelenburg Posture.

If Trendelenburg's posture is to be used, an especial table or appliance is necessary. Cleveland's table is the most complete.

A table of glass and iron is the best for a regular operating-room, as it can be easily washed. In any case, contact between the table and operator should be prevented by sterile sheets or towels. Kelly's pads provide drainage for fluids.

Towels.—Sterilized towels are very extensively used in surgical operations. Two or three dozen good-sized ones are not too many for such an operation as the removal of the breast and axillary contents. They should cover the patient's blankets from the feet up. They should be placed about the field of operation so as to protect implements and hands from contact with any unsterilized substance, and these should be removed from time to time. The ether cone should be covered with one. They should be pinned in front of the surgeon's gowns. They should cover the tables, and they should be used to cover the hands when it is necessary to lift or move any unsterilized object, such as a dressing-case or the cautery. The irrigators, the bowls for solutions, etc., should be enveloped in them. Their use in all these instances is a very great safeguard against infection.

The questions arise, When is a towel aseptic? What are the best methods for making it so? Behring made a study of the sterilizing effect of the methods which are used in the laundry. A common method of washing linen articles is to put them into hot water which contains about $1\frac{4}{10}$ per cent. of washing soda. If this is raised to a temperature of 175° to 185° F. its germicidal power is very great. He found that at 185° F. anthrax spores were killed with certainty in from eight to ten minutes, and that they were frequently killed in four minutes. Since anthrax spores are far more resistant to germicides than the ordinary pyogenic bacteria, we may feel that all towels or pieces of linen which are subjected to immersion in this hot soda solution for ten or fifteen minutes are sterilized by it. They may, however, become infected later; and again, we can never feel certain that all the towels go through this process. Some may not get into the hot solution at all, and in some laundries the washing of towels consists in dipping them in hot water and hastily scrubbing them on a washboard for a few seconds or minutes. Hence, in addition to the laundering, towels should be boiled in the operating-room five to ten minutes, or steamed in a steam sterilizer fifteen to twenty minutes, or submerged in a warm 1 to 1,000 solution of bichloride of mercury for half an hour or more.

For sterilizing by steam, Arnold's steam sterilizer is efficient in nearly every instance; it has the advantage of being cheap. A more expensive but better form of sterilizer is that shown in the cut, which has the advantage of drying the sterilized objects without removing them.

Instruments. — Instruments are best sterilized by boiling them for five to fifteen minutes in one per cent. watery solution of washing soda.

This does not admit of much discussion; the method is so great an improvement on the ones formerly used that it should be universally adopted. It is somewhat amusing that, after all the years of study that have been given to the preparation of surgical instruments, and the thousands of instruments which have been

FIG. 688.—Cleveland's Operating-table, with Patient in the Trendelenburg Posture.

ruined by steam and strong chemical solutions, we should at last find that our best instruments are best treated just as our washerwoman treats our clothes. Davidsohn im-

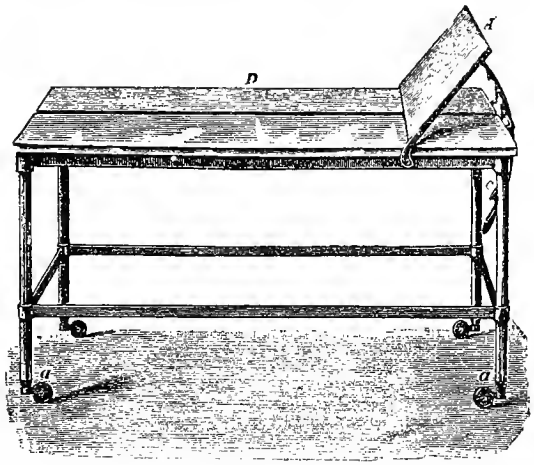

FIG. 689.—Plain Glass and Iron Operating-table. The head-rest is unnecessary.

pregnated threads with anthrax spores and put them into a little hole in a piece of lead, and boiled it all for five minutes in water; it was sterile. He then repeated the

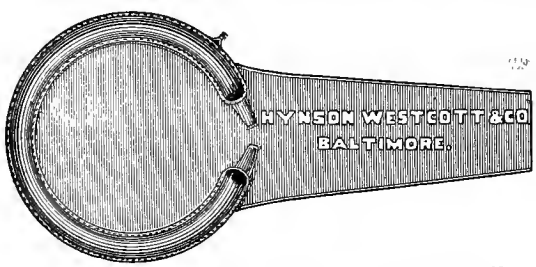

FIG. 690.—Kelly's Pad or Surgical Cushion. See also cut No. 685.

experiment and used pus and pyogenic bacteria, and put them into instruments, catheters, syringes, etc., as well. He found that after five minutes' boiling sterilization was regularly complete. Schimmelbusch continued the

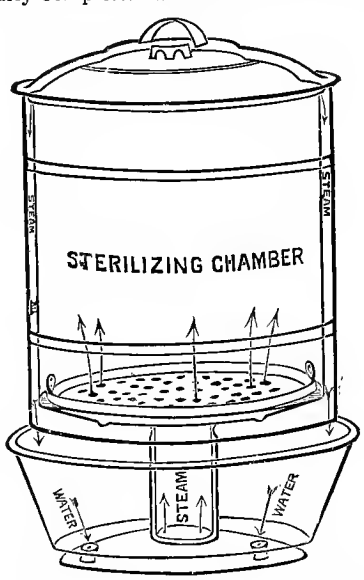

FIG. 691.—Arnold's Steam Sterilizer, Showing the Course of the Steam.

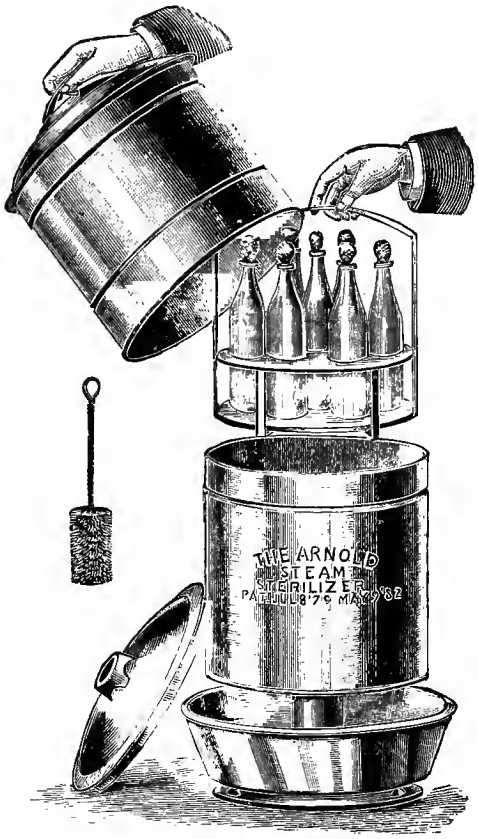

FIG. 692.—Arnold's Steam Sterilizer.

studies, adding one per cent. of washing soda to the water. He impregnated silk threads and thick woollen

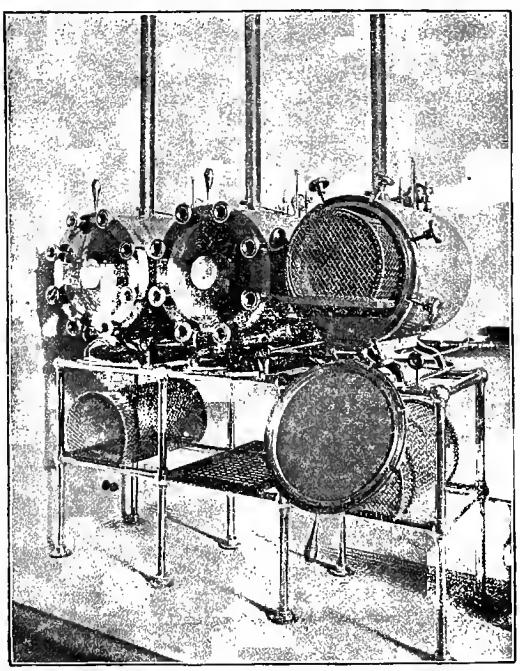

FIG. 693.—Sterilizers for Sterilizing Dressings by Steam under Pressure and Drying them without Removing them from the Sterilizer. Syms's Operating Theatre of Roosevelt Hospital, New York City.

threads with pus and pure cultures of staphylococcus pyogenes aureus, bacillus pyocyaneus, and anthrax spores, and then dipped them for varying lengths of time in the boiling one per cent. soda solution. He found that the pus, the staphylococci, and the bacillus pyocyaneus were killed in from two to three seconds, and the anthrax spores in two minutes.

Thus we see that in the boiling soda solution we have one of our strongest germicides. The method has been very extensively and satisfactorily used since the publication of Schimmelbusch's article in 1891. It has the very great advantage that it prevents rust. Instruments which are regularly cleaned in this way, and kept in a dry place when not in use, are almost as bright as new. This is important, as surfaces which are made uneven by rust are apt to harbor bacteria. Repeated boiling in soda solution injures wooden-handled instruments.

The method is remarkably convenient, as in every household there is water, a stove, and washing soda, or some alkaline washing compound which is equivalent to it. If need be, the instruments may be immersed in this soda solution in an ordinary covered pan, and then boiled on the stove for five or ten minutes. All may then be removed from the stove and allowed to cool while the other preparations for the operation are going on. The instruments may be used directly from this solution without being transferred to any other pan.

For regular use, however, a sterilizer should be constructed in which the solution may be kept boiling during the operation, so that it will be possible to sterilize any instrument which has not been prepared, or which has come in contact with an unsterilized object. Agate-ware asparagus boilers or fish-kettles make very good sterilizers (see Figs. 694 and 695). The asparagus boilers are $10\frac{3}{4} \times 7\frac{1}{4} \times 6\frac{1}{2}$ inches in size, and hold any of the ordinary instruments and enough of them for an ordinary operation. Each contains a movable tray upon which the instruments may be transferred to an instrument-pan, which should contain sterilized water. These boilers are so small that they may easily be carried in a hand-satchel. They may be packed full of implements, and hence do not use up a great deal of space. They, or something which takes their place, may be used to advantage in all operations and in every surgeon's office. The instruments may be held in a bag or towel if there are too many of them to be lifted on the tray without falling off.

FIG. 694.—Agate ware Asparagus Boiler for Sterilizing Instruments.

FIG. 695.—Agate-ware Fish-kettle for Sterilizing Instruments.

Knives are somewhat dulled by this boiling in soda solution. Schimmelbusch recommends the following method of sterilizing them: They should be smooth and have metal handles. They should be thoroughly rubbed with sterilized gauze soaked in alcohol or ether; after they seem to be thoroughly cleaned they may be dipped in the boiling soda solution for a few seconds. This is sufficient to kill the ordinary pyogenic bacteria. It seems to me to be an advantage to precede this dipping in soda solution by a preliminary boiling of the handles for five minutes in the same solution. This may be accomplished by standing the knives in a wire rack, so that the blades may project from the solution. The blades are not materially dulled by this preliminary boiling. By this method the pyogenic bacteria are killed. It will not kill the more resistant germs, such as anthrax spores, but it is not at all likely that such spores will exist on instruments so prepared.

All instruments should be of as simple construction as possible, and should have metal handles. Locks which allow the two parts of forceps-like instruments to be separated are desirable.

Syringes.—Syringes should be sterilized by boiling them in water or soda solution when possible. Schimmelbusch infected hypodermic syringes by drawing into them pus and cultures of staphylococcus pyogenes aureus and bacillus pyocyaneus, and then experimented with different ways of sterilizing them. He found that after boiling water had been drawn in and expelled five times they were germ-free. After drawing in and expelling three per cent. carbolic solution ten times, he obtained more than five thousand bacteria from them.

Sutures and Ligatures.—For sutures and ligatures five substances are in common use: Silk, silk-worm-gut, silver wire, horse-hair, and catgut.

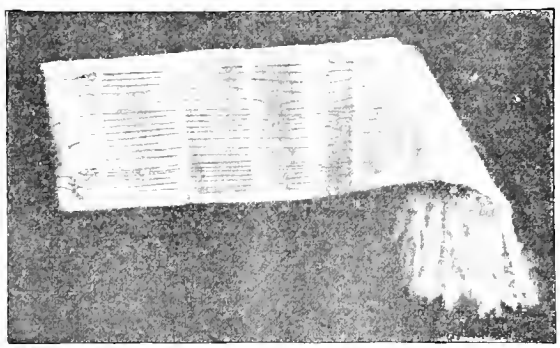

FIG. 696.—Needles and Thread for Intestinal Sutures, Fastened in a Towel, Ready for Sterilization.

Silk is used for skin and intestinal sutures, and for ligatures where there are distinct pedicles, as in ovariotomies, and by some surgeons it is also used for the ligation of blood-vessels, large and small. Its advantages are that it is easily sterilized, is very pliable, and it will not slip after it has been properly applied and knotted. Its great disadvantage is that it easily becomes infected in the wound, and then is a source of great irritation. Stitch-hole abscesses are more common with silk sutures than with sutures of a hard substance like silk-worm-gut, and on examination it has been found that they more frequently contain bacteria.

As long ago as when Marion Sims was working over vesico-vaginal fistulæ, he found that he could close fistulæ with silver-wire sutures which he could not close with silk ones. The abdominal sinuses which sometimes remain after laparotomies are usually due to infected silk ligatures, and after the ligature comes away the sinus closes. Silk may be sterilized by boiling in one per cent. soda solution five to ten minutes, or by being steamed in a sterilizer fifteen to thirty minutes. This may be well done on bobbins in tubes; the silk will remain sterile so long as it is left in the tubes, if the cotton plugs are left in. In preparing fine silk for intestine work, it should be threaded before it is sterilized, and then arranged on towels and boiled with the instruments, or steamed with the dressings. It is always better to prepare the silk, so far as possible, for each operation, and not to subject it to the dangers of infection which come from keeping a large reel of it and using pieces of it from time to time. It may, however, be kept permanently sterile on small bobbins in cotton-plugged test-tubes which have been sterilized by steam.

Silk-worm-gut is an excellent material for skin sutures and is coming more and more into favor. It is hard and smooth, and hence is free from little crevices and meshes

which harbor discharges and favor bacterial growth. It is easily tied and easily prepared. Wounds sewed with it heal more kindly than those sewed with silk. It may be sterilized by steam in cotton-plugged test-tubes and kept ready for use, or it may still better be boiled with the instruments in the soda solution.

Silver wire is unirritating, just as the silk-worm-gut is. It is used of a larger size than the silk-worm-gut, and can be tightened by twisting and shaped by binding. This is an advantage in such operations as trachelorrhaphy, and its strength is an advantage in closing abdominal wounds. It should be sterilized in boiling soda solution with the instruments.

Horse-hair is also unirritating, as are silver wire and silk-worm-gut, and is so small that it is well adapted to the sewing up of small skin incisions, especially about the face where a scar is to be avoided. It should be selected from the back of a horse's tail, where it has come in contact with neither fæces nor urine. It should be washed in soap and water and then boiled in strong alcohol for an hour.

Catgut is not well fitted for skin sutures; as it becomes disintegrated it favors bacterial growth. It is, however, the ligature material which is most generally used both for the small vessels which are clamped and tied in ordinary operations, and for large vessels. Some operators use it for the tying of the large pedicles of tumors as well. Catgut is absorbed in the tissues. The length of time which this takes varies widely. When catgut stitches are taken in the skin they usually come away in about a week, but bits of hardened catgut have sometimes been found in the tissues months after operation. The proper preparation of catgut is a problem which has long puzzled surgeons. Few are willing to use the gut which is sold already prepared in the shops. The general feeling is that its preparation should only be intrusted to those who have had a regular training in aseptic and antiseptic methods, and who have a personal responsibility for the welfare of the patients. Furthermore, sterilization by immersion in chemical solutions is coming into much disfavor. Heat, or heat and chemical action combined, are found to be more convenient and more efficacious in almost all instances. Catgut, however, can neither be boiled in water nor exposed to steam without being rendered useless, and the suitable application of dry heat is difficult.

Dr. George R. Fowler, of Brooklyn, has found that if catgut is boiled in strong alcohol it is sterilized, and is stronger than that prepared by chemicals. The boiling-point of the alcohol used was 175° F. This heat, together with the action of the alcohol, sterilizes the gut in an hour or less.

Dr. Hodenpyl made a series of experiments to test the efficacy of this method, and obtained the following results: Unsterilized catgut regularly contained bacteria. Commercial catgut is generally sterilized by five minutes' boiling in strong alcohol; it was always sterile after an hour's boiling. Catgut impregnated with streptococcus pyogenes, staphylococcus pyogenes aureus, and the anthrax bacillus, was sterilized in fifteen to thirty minutes, and that impregnated with anthrax spores in forty-five minutes, by boiling in strong alcohol. These experiments gave scientific proof of the germicidal power of boiling alcohol.

For the purpose of adding further evidence on the subject, I repeated Hodenpyl's experiments with gut which was impregnated with pus which was a pure culture of streptococcus pyogenes, and pus which also contained staphylococcus pyogenes aureus, and I obtained similar results.

Catgut which has been boiled for an hour in alcohol is considered aseptic, and has been much used since the publishing of Dr. Fowler's article. His method, or some slight modification of it, has been satisfactorily employed, for times varying from two years to a few months, in St. Luke's Hospital, Roosevelt Hospital (Out-patient Department), and the Cancer Hospital in this city, in some of the Brooklyn hospitals, and by many surgeons in their private work. The only valid objection made to it, so far as I know, is the difficulty in preventing the undue evaporation of alcohol. If it is boiled in an open jar, or one with the cover a little raised, the evaporation is so rapid that the alcohol is wasted and the gut becomes uncovered unless carefully watched. If the cover of the jar is tightly screwed down we may hope that the alcohol will boil at 175° F. to 177° F., and that not more than one-fifth of its volume will evaporate in an hour's boiling. Such a result will usually follow, and the catgut may be efficiently prepared in this way. A cold object, such as an ice-bag on the top of the jar, aids in the recondensing of the alcohol. This method, however, has serious objections: On the one hand, the leakage may be more than one-fifth of the alcohol; on the other, the jar may be so tightly sealed as to allow the alcohol to rise to 195° F. or 200° F., and the gut is rendered useless by an hour's exposure to this temperature. It is far better to boil the alcohol under ordinary atmospheric pressure, and then recondense it. This gives a constant temperature and very little liability to mishap. Hence, very small-sized gut may be used with the knowledge that it will be strong after the preparation.

The accompanying apparatus is the simplest I have yet seen: A condenser (Fig. 697) is made by encasing a coil of block-tin tubing in a cylinder of sheet copper. The height of the cylinder is seven inches; its diameter three and one-half inches. The length of the tubing over all is four feet; its internal diameter, one-eighth inch. A piece of the tubing, five inches in length, projects from the top of the cylinder, and is shaped into a hook. A straight piece, two inches in length, projects from the bottom. The condenser may be suspended by this upper hook, or may rest on a retort-stand or tripod. Two taps are inserted into the cylinder for the transmission of water in and out. The lower one is attached by rubber tubing to a faucet for running water, the upper one is fitted with a rubber tube to provide for the escape of the water. Where running water is not convenient the cylinder may simply be filled with cold water, and that will suffice for recondensing the alcohol evaporated in an hour's boiling. The catgut is put into alcohol in such a jar or bottle as is convenient. The piece of block-tin tubing at the bottom of the condenser is fitted into a perforation in the cork of this bottle or jar. A water-bath is made by placing a small basin of water on a gas-stove or over a Bunsen burner. The apparatus should be so placed that the jar which contains the alcohol is partly immersed in the water (Fig. 698). Heat is then applied to the water-bath until the alcohol boils. It may be kept boiling as long as is desired, without especial attention and with no loss of alcohol, since it is recondensed as fast as it is vaporized and drops back into the bottle. The capacity of the condenser is such that the vapor from a quart of alcohol is condensed as rapidly as it is produced by ordinary boiling. It is not necessary to boil the water or the alcohol so vigorously as to force it through the condenser. The alcohol after an hour's boil-

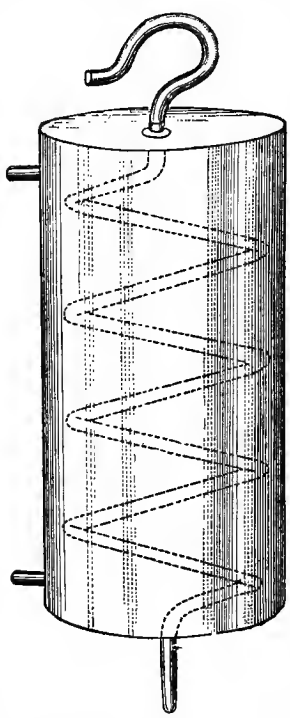

FIG. 697.—Condenser for Recondensing the Alcohol Evaporated in the Sterilizing of Catgut.

ing and recondensing shows no trace of either tin or lead from the tubing. A bit of absorbent cotton should be inserted in the upper end of the tubing.

The apparatus may be obtained from the W. F. Ford Surgical Instrument Co., Thirty-second Street and Fifth Avenue, New York City.

This method puts within the reach of every surgeon an easy and efficient way of obtaiuing catgut which is aseptic, and which is pliable and strong. For the ligation of the smaller vessels, such as are tied in an ordinary operation, gut No. 00, about the size of spool cotton No. 10, is strong enough. For such vessels as the anterior tibial the diameter of the gut should be about twice as great. It is believed that boiling alcohol is much more efficient than any chemical antiseptic solution which weakens the catgut so little.

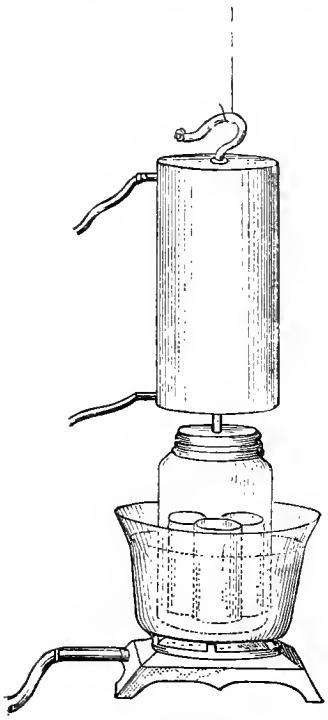

FIG. 698.—Apparatus for Sterilizing Catgut.

Oil or fat is a great protection against the action of chemical solutions. Catgut is regularly greasy before it has been bleached, and in the process of twisting it much of the greasy surface is turned into the interior of the strand. It is thus particularly difficult to destroy the life of the bacteria or spores which are carried within the strand in the twisting, and are there more or less protected by fatty matter. Boiling alcohol is a strong solvent of fatty matter, and is thus especially well fitted to penetrate the small crevices in the catgut, and so to bring the germicidal action of the heat and the alcohol to bear on all contained bacteria and spores. Heated liquids seem to have remarkable germicidal power, as has been already indicated. If we turn to the table on page 1041 we shall see how great a sterilizing power liquids have when heated to 175° F.

Judging from the results expressed in the table, we would expect that the ordinary pyogenic bacteria would be killed in boiling alcohol in five or ten minutes, anthrax spores in about half an hour. This corresponds well with Hodenpyl's results. Hodenpyl used ninety-seven per cent. alcohol with a boiling-point of 175° F. I have found that the boiling-point of the ninety-five per cent. alcohol obtained from a reliable druggist is about a degree higher. The more water there is in the alcohol the higher is the boiling-point, the greater the germicidal power when boiling, and the greater the injury done to the catgut by the process.

Although, according to Fränkel, anthrax spores are considered the most resistant of infective agents, it is important that the medium which is used for sterilizing the catgut should be capable of killing them, since there is always a possibility that they may exist in the sheep's intestine, from which the so-called catgut is prepared. Volkmann has reported two cases where anthrax pustules appeared in wounds at the points where catgut sutures were taken. He thought the infection due to the catgut.

Another advantage in this method of boiling in alcohol comes from the ease with which infection of the catgut may be prevented after it is once sterilized. Professor Halsted has devised an excellent method of sterilizing his silk ligatures and sutures, on bobbins in test-tubes, and using them one by one as needed. A somewhat similar device may be used for catgut. Glass reels are made, each half an inch long, with flanges one inch in diameter, which are so shaped that the ends of the reels are concave. Two or three yards of gut can be wound on each without overlapping enough to prevent the free access of the alcohol. Three of them fit, one above the other, in a small cylindrical screw-topped jar. Rubber washers are fitted into the covers of these jars, and they, containing reels of catgut, filled with alcohol, and having the caps screwed on, are put, four at a time, in a quart Mason preserve-jar. The jar is then three-fourths filled with alcohol, attached to the condenser, and put in the water-bath. After an hour's boiling the small jars are taken out and their caps tightened. Each reel may be taken from the jar as it is needed. The surgeon holds it in his left hand and unrolls the gut as he ties the ligatures. It unrolls easily if the reel is held loosely between the thumb and third finger so that the nails are in contact with its concave ends. The flange protects the gut from contact with any foreign substance until it is unwound. Thus, from the time the gut is sterilized until it is applied in the wound the only foreign substance which it touches is the hand of the surgeon. It is not exposed to infection from contact with perforated stoppers, necks of bottles, scissors, forceps, towels, gowns, hands of assistants, etc. That which remains in the jar has not been disturbed. It is not difficult to tie the ligatures with the reel in the hand, if the hands are crossed in tightening either the first or the second half of the knot.

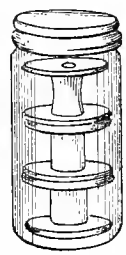

FIG. 699.—Small Jar Containing Reels for Sterilized Catgut.

Catgut may be efficiently prepared in other ways. In von Bergmann's clinic, in Berlin, the following method is used:

1. Sterilization of the glass dish which is to hold the gut, for three-quarters of an hour in steam.
2. Winding of the gut on glass spools or plates.
3. Cover the gut with ether and let it stand for twenty-four hours.
4. Pour off ether and pour on the following solution:

Bichloride of mercury	10 parts.
Absolute alcohol	800 parts.
Distilled water	200 parts.

5. Renewal of the sublimate alcohol daily; after the second renewal sterilization is complete.
6. Exchange the sublimate alcohol for ordinary alcohol. If twenty per cent. of glycerine is put in this last alcohol the gut is hardened.

For such operations as Hegar's perineorrhaphy and Bassini's operation for the cure of hernia, a very hard gut which cannot be easily absorbed, is needed. Macewen's chromicized gut is the kind used. It is prepared as follows: Put the gut overnight in the following solution:

℞. Acid chromic	ʒ iij.	ʒ vss.
Aquæ	Oj.	
Then add with care,		
Glycerine	Ov.	
M.		

Store the gut in a five per cent. solution of carbolic acid in glycerine.

Some surgeons do not believe that this sterilizes the gut. It is wise to extract the fatty matter by alcohol and ether before immersing it. The solutions may be used warm.

Drainage-tubes, whether of rubber or glass, should be prepared as the instruments are, by boiling in soda solution. Sponges or wipers of some kind for absorbing the blood or fluid discharges must be used in nearly all operations, and since these come in such close contact with the wound, the greatest care is necessary in their preparation. Sponges absorb the blood more quickly and thoroughly than any other material now in use. The great disadvantage is that they are expensive, and are usually washed by an assistant time and again during the opera-

tion, as they become bloody. This manipulation very materially increases the chances of infection. It furthermore makes additional nurses and assistants necessary. Pads of sterilized absorbent gauze, or little balls of sterilized cotton encased in absorbent gauze, make very

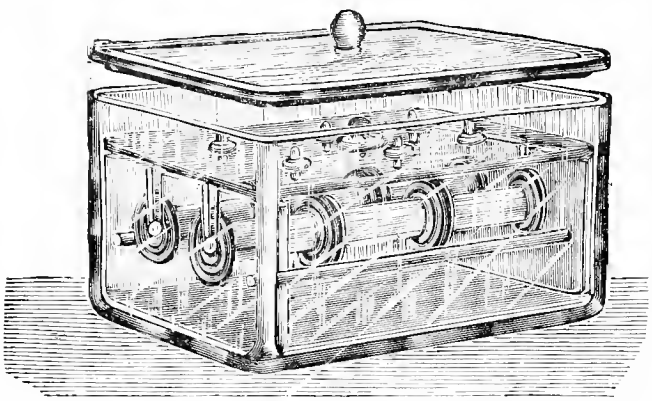

FIG. 700.—Glass Dish for Keeping Catgut in Operating-room in Alcohol.

good wipers. The pads should be made each of a piece of gauze about twelve by twelve inches in size, so folded that the cut edges are all turned into the interior of the pad, so that threads need not be left in the wound. When folded they should be about three inches square. They are encased in a towel or put in cases (see Fig. 701), and sterilized in steam by an exposure of from thirty to sixty minutes. They should be placed within the reach of the surgeon and his assistants, and should come in contact with absolutely nothing between sterilization and use. Each pad is thrown to the floor after it is used. About two or three dozen are used in such an operation as the removal of a breast and axillary contents. For an amputation of a leg eight or ten may suffice. Richardson and Mumford, of Boston, use these pieces of gauze without folding in the edges, and consider that the threads which come away from the edges are not important. The danger of sepsis is less from these pads than from sponges, but they are not good for the abdominal cavity, because they become so easily doubled up into wads, nor for such operations as the removal of the jaws, where we need something which can be easily managed on holders, and which will absorb blood very rapidly. Sponges should be used for such purposes. There are several methods of preparing them.

The so-called permanganate-of-potash method is one which is much used. The sponges are first thoroughly washed and beaten, and then put into a 1 to 500 solution of potassium permanganate for twenty-four hours. They are then put into a one per cent. solution of hyposulphite of soda, to which eight per cent. of hydrochloric acid is added. They remain here until bleached, and are then washed and transferred to a five per cent. solution of carbolic acid, in which they are kept. Fritsch found that twenty per cent. of the sponges so prepared in Billroth's clinic contained germs.

Kelly prepares his sponges in the following way: Some of the handier ones are carefully washed in many waters, until the water is no longer discolored. Then, after immersing them for twenty-four hours in a weak solution of hydrochloric acid, two drachms to the pint, to dissolve out the chalky particles, they are put in the sterilizer for twenty minutes. But few sponges will stand this, however. The usual method is to transfer them from the hydrochloric solution to distilled water, in which they are washed until the water remains clean. They are next immersed in a 1 to 1,000 bichloride solution for twelve hours. They are taken from this and rinsed in warm distilled water, and then put in large lots in big jars in a three per cent. solution of carbolic acid. It is particularly unfortunate that sponges cannot be boiled in water or steamed long without becoming hard and shrunken.

Schimmelbusch recommends the following method: The sponges should be beaten and washed and kneaded several times, in both cold and warm water, to clear away the sand, shells, and dirt. They should then be pressed together in a linen cloth, or in a bag made for the purpose, and put into a large pot of boiling one per cent. soda solution which has just previously been taken from the stove. They should remain immersed in this solution half an hour. The heat of this gradually cooling solution is not sufficient to injure the sponges materially. It is, however, enough to sterilize them, according to the investigations of Behring, Freeman, and Van Geuns. Schimmelbusch found that sponges that were saturated with anthrax spores and with pus were sterile after ten minutes' immersion in this hot soda solution. They may be transferred to boiled cooled water in the sack which contains them, to be freed from the soda, and then be kept in an antiseptic solution—preferably corrosive sublimate, 1 to 2,000. They turn dark in carbolic solution, also in the sublimate solution, if they have been previously treated with sulphuric acid. The method is simple and has the great advantage that there is little handling of the sponges after the process of sterilization is really begun.

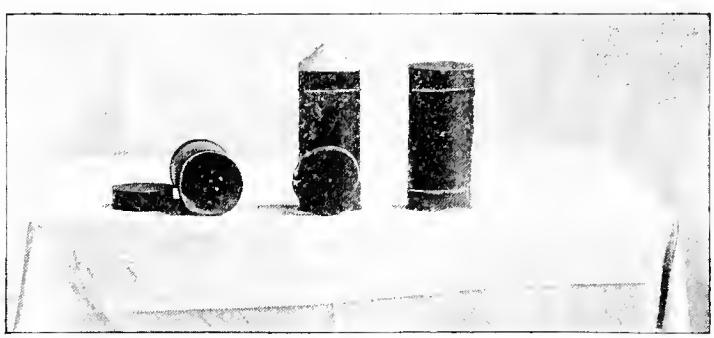

FIG. 702.—Metal Cylinders for Holding Sterilized Gauze and Cotton.

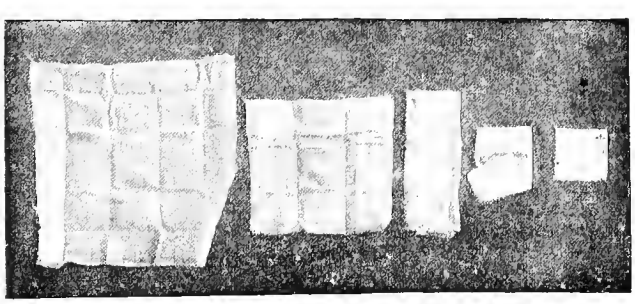

FIG. 701.—Absorbent Pad (a substitute for sponges). The figure at the right shows a gauze pad folded in readiness for absorbing the blood in a wound. The other figures show the stages of folding.

Dressings. — Surgical dressings are becoming more and more simple all the time. Absorbent gauze is the material most used. The requirements of a good dressing are that it shall protect the wound without irritating it; that it shall absorb discharges, and that it shall prevent bacterial growth. Sterilized gauze combines these qualities to a remarkable degree. The commercial name of the gauze is butter-cloth. It is a bleached

cheese-cloth. It should be so absorbent that a bit of it thrown on water will sink immediately; and if one end of a little twist of it is dipped in a glass of water and the other end allowed to hang over the edge of the glass, the water should drip from the hanging end. A strip of gauze 1½ by 8 inches should in this way lower the level of the water in a tumbler 1½ inch in half an hour. This gauze is best prepared by steaming for forty-five minutes or more in a sterilizer. After sterilization it should come in contact with no object until it is used. A convenient method is to have some cylindrical boxes made (see Fig. 702), 4 inches in diameter and about 10 inches long; the bottom is raised and is perforated to facilitate the access of the steam to the gauze. A layer of absorbent cotton is put on the bottom of the box, a roll of gauze above this, and again a layer of cotton above the gauze. The box is uncovered in the sterilizer, but the cover should be sterilized with the rest and applied after the box is taken from the sterilizer. The gauze dries if the box is put near a Bunsen flame or a gas-stove. It is, however, not very moist at any time. Enough gauze can be put in one of these to cover any ordinary wound. They can be carried easily to the hospital wards or to the house of a patient without contaminating the gauze. An ordinary glass fruit-jar makes also a very good receptacle for sterilizing the gauze and carrying it about. This gauze may be used for our inside dressing. It meets our first requirement, it protects the wound without irritating it. Its absorbing power is great, and hence it meets our second requisite of a good dressing.

Does it fulfil the third? Does it prevent bacterial growth? Yes, to a very marked degree so long as it is dry. If the discharge from the wound is so great as to saturate the dressing and keep it wet, the absorbent gauze is not germicidal; if, however, it absorbs the discharge and quickly dries it, bacterial growth is prevented, since dryness is one of the greatest inhibitors of bacterial development. Schimmelbusch states that "there is no agent which hinders decomposition of the wound secretion in a dressing more simply, harmlessly, and promptly than does dryness, the evaporation of the products of secretion." "Moisture is the peculiar life-principle of the lower organisms, dryness their greatest foe." Schlange demonstrated by experiments how rapidly the drying of gauze stopped bacterial growth in it. He saturated pieces of sterile gauze with nutrient bouillon and infected them on the surface with the green pus fungus. The impregnated pieces of gauze were laid in glass dishes. When the dishes were uncovered so that evaporation was free, there was little growth of the mould. When these dishes were covered so that evaporation was hindered, the bacillus grew rapidly, and soon the green color extended all over the piece of gauze. If the green growth was allowed to extend about half an inch and the dish was then left uncovered, in a short time the dryness of the gauze prevented further growth.

In von Bergmann's clinic, in Berlin, these sterilized dressings have been used for years with great satisfaction. They have also been used in numerous hospitals and by many surgeons in this country and abroad. I have found that wounds in which there was a slight discharge healed more quickly under them than under dressings which are saturated with chemical germicides. If these germicides are strong enough to stop bacterial growth, they are injurious to the tissues about the wound. Certain classes of wounds, such as incisions for spreading cellulitis, need wet dressings, and for these simple sterilized gauze is not suitable. But for fresh wounds, which have no inflammation of the cellular tissue about them, it seems to be the dressing *par excellence*.

Those wounds in which there is a thick purulent discharge which cannot be absorbed by the gauze do not do well under simple sterilized dressings. The thick pus stays about the opening of the wound, and retards its rapid healing. For such wounds as this, iodoform gauze is the most suitable dressing. Iodoform has held its place in surgery in spite of all the attacks which have been made upon it. Its best use seems to be in those cases where there is a purulent discharge. The iodoform in combination with such a discharge gives up its iodine and so prevents excessive putrefaction. There are many fallacies about iodoform gauze as it is frequently used. It is exposed to all sorts of infection in the progress of preparation, and frequently becomes contaminated in the holders in which it is kept. It seems hardly rational to put in close contact with fresh wounds gauze which has been handled in a careless way by druggists' clerks, and which has perhaps been hung on clothes-lines to allow the evaporation of the benzine. The gauze, after it is prepared, cannot be sterilized by steam or heat without largely decomposing the iodoform.

The iodoform gauze should be prepared by the surgeon or his assistant by moistening sterilized gauze with boiled water, and then rubbing dry powdered iodoform into it, on a sterilized cloth, with a sterilized piece of gauze or roller bandage. It should not be prepared from a solution of iodoform in ether, for the iodoform is then easily decomposed; nor should an emulsion of glycerine be used, since the glycerine diminishes the absorbing power of the gauze. Sterilized absorbent cotton prepared like the gauze is usually put outside of it to protect it from contamination, and to absorb any fluid which may come through the gauze. Bandages of gauze or mull should be sterilized in steam. Those of muslin, crinoline, or plaster, need not be sterilized, as they are applied at a distance from the wound.

A protective dressing of rubber tissue is frequently applied immediately over wounds to protect healing tissues from mechanical violence. This is best sterilized by immersion in a 1 to 1,000 sublimate solution for several hours. It should be dried before application.

There are numerous other substances which have been used in surgical dressings, but the surgeon need seldom use any which are not mentioned above.

In applying the dressing enough should be put on to cover the wound thoroughly and protect it from any possible external infection. Usually pressure over the wound and restriction of motion about it should be obtained. The putting on of an insufficient dressing is a very common mistake.

The accompanying cuts show neck and breast bandages in position.

FIG. 703.—Dressing Applied after the Removal of a Tumor of the Neck. New York Cancer Hospital.

Solutions should be prepared from water which has been boiled. It is an advantage to have it filtered before the boiling. It should not be exposed to any sources of infection after the boiling. The simplest method is to boil the water in flasks which are plugged with cotton, and which are not opened until the time of operation. Where large quantities of water are needed, an apparatus is made by which the water may be boiled and then cooled by running cold water through a coil of pipe which is in the boiler. Since solutions of weak antiseptic power are so much in vogue, it is eminently unsuita-

ble to expose them to dangers of infection by transferring them into various receptacles, or by cooling them, or diluting them with unsterilized water.

Dishes.—Dishes which are used in the operating-room should all be sterilized. This is best done by boiling them in soda solution. If this is inexpedient, they should be put in a pot or pail of hot soda solution, as the sponges are. If this cannot be done, they may be thoroughly washed and then filled with hot 1 to 100 sublimate solution which should be left in half an hour or more. Any adherent sublimate may be washed away in hot water.

FIG. 704.—Dressing Applied after Removal of Breast and Axillary Contents. (Schimmelbusch.)

In the final preparation for an operation one may frequently wish to be delivered from one's friends. It is astonishing how often medical men come to the operation and wish to grasp the hands which have just been sterilized with so great care, or to touch the patient or implements about the room. The density of ignorance which these men show is well illustrated by the rejoinder of an attending physician in a neighboring town, who, when warned away from the patient by the consulting surgeon, exclaimed that he was not afraid, as he had never received any injury from touching either the patient or instruments ! ! !

It is clearly one's duty, unpleasant though it be, to prevent this form of contamination. Throughout these preparations cleanliness is the one underlying principle. If we can keep everything surgically clean, our wounds will heal quickly and kindly. It is far better to do this than to allow infection and then attempt to remove it by strong chemical solutions which injure the tissues and diminish their power of repair.

When operations are to be done in private houses, it often becomes a question as to how these somewhat bulky appliances are to be made portable. The accompanying cut shows an arrangement of instruments and implements which would avail for such an operation as the amputation of a leg.

FIG. 706.—Appliances to be Packed in Satchel for an Operation such as the Amputation of the Leg.

1. Cylinder containing sterilized gauze for dressing.
2. Cylinder containing sterilized cotton for dressing.
3. Cylinder containing sterilized pads for absorbing blood from wound.
4. Jar of sponges (probably not to be used).
5. Gown for operator.
6. Roller bandages.
7. Rubber adhesive plaster.
8. Esmarch bandage.
9. Tablets of corrosive sublimate.
10. Catgut ligatures.
11. Catgut ligatures.
12. Sterilized silk.
13. Safety-pins.
14. Silk-worm-gut (sterilized).
15. Carbonate of soda for boiling instruments.
16. Sterilized drainage-tubes.
17. Iodoform gauze (probably not to be used).
18. Instruments contained in roll.
19. Needles.

Dishes and a boiler for the instruments may be supplied at the house or may be sent by the surgeon.

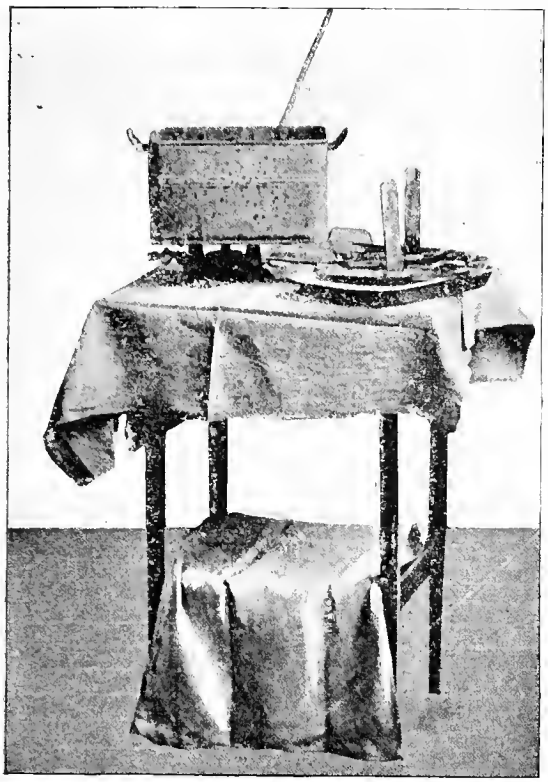
Fig. 706 shows a convenient arrangement.

FIG. 705.—Cotton-plugged Flasks of Sterilized Water.

II. THE OPERATION ITSELF.

The operation itself calls for as great care as do the preparations. By following out the rules which have been given, the operation may be begun in aseptic *régime*. One great difference between the preparation for the operation and the conducting of the operation is, that the former may usually be done leisurely, while the latter must frequently be done hurriedly, and by some unguarded action sepsis creeps in. Hence, in planning our operative technique we should endeavor to have our sterilized implements untouched between the time of sterilization and the time of their use in the wound. Our catgut, our gauze pads, some of our instruments, and some of our sutures need touch no object between the time of sterilization and their use in the surgeon's hands. The principles which make this possible should be applied wherever they can be. The fewer hands which go into the wound, the better. The fewer hands which touch the instruments or implements, the better. The greater the extent to which assistants can learn to retract tissues

and make it easy for one man to do the actual cutting, clamping, and tying, the fewer are the chances of infection. Infection often creeps in during the operation,



1 2
3

FIG. 707.—1. Instrument boiler with its tray removed, containing the instruments which are to be transferred to 2, Instrument pan. 3. Portable gas-stove.

owing to unguarded contact with objects which have not been sterilized.

No new principles are to be considered in this regard. Those already laid down, however, are to be followed with the strictest care. If, for instance, an instrument is to be taken from the case and used, a sterilized towel should be put over the hand and the instrument transferred to the boiling soda solution, where it is sterilized before using. I once took from an instrument-case a pair of artery clamps which had been carefully washed and put away. I have reason to believe that they were as clean as instruments usually are in an instrument-case; yet when they were covered with nutrient gelatine about fifteen hundred bacterial colonies grew from them. If such forceps were handled by assistants or by the operator, a large avenue of infection would evidently be opened. In the same way a cautery, unsterilized dressing-boxes, ether bottles, etc., must on no account be touched by the operator or an assistant who handles instruments or sponges. If such implements are to be used, a sterilized towel or pad must be put over the hand. Towels so used should be thrown to the floor and not handled again. Instruments which fall to the floor are manifestly unfit for use until further sterilization. Warm sublimate solutions should be so placed that the hands may be conveniently washed in them from time to time. Towels should be renewed as they become soiled. Ligatures or sutures should be so short that they need not drag on towels, or unnecessarily come in contact with any foreign body.

It frequently happens in an operation that pus is evacuated, and still it is important to have aseptic conditions following, so far as is possible. For instance, a pustule, an ovarian or perityphlitic abscess is opened in the abdominal cavity; this pus is often virulently infective, and if instruments and sponges are contaminated with it and are then used on the peritoneum and about the abdominal wound, we must fear sloughing of the wound and peritonitis. When pus appears in this way it should be quickly collected on sponges, towels, or gauze, and if the tissues are touched by the pus they should be carefully wiped off, and all instruments, sponges, etc., which have touched the pus should be immediately removed. The instruments should be washed and resterilized if they must be used again; the other things should be thrown aside. All hands should be thoroughly washed again, fresh towels should be put about the patient, and the operation may then be continued as before. The advisability of washing out the abdominal cavity after such an occurrence is a disputed question. The weight of evidence is in favor of washing it out with warm six per cent. sodium chloride solution.

During the operation the surgeon has continually to consider questions apart from the aseptic technique which we have been dwelling upon. We have already stated that there are two opposing forces to be dealt with, viz., 1. The growing power of the bacteria; 2. The repairing power of the system. In the operation it is necessary to consider the second as well as the first.

One must continually give heed to: 1. The proper limitation of the constriction, laceration, and chemical and mechanical injury of the tissues. 2. The management of dead spaces. 3. The use of drainage. 4. Irrigation.

Tissue which is constricted is prone to suppuration far more than that which has a good circulation. Welch reports a case in which there was fatal peritonitis, which started from a volvulus which had become infected with

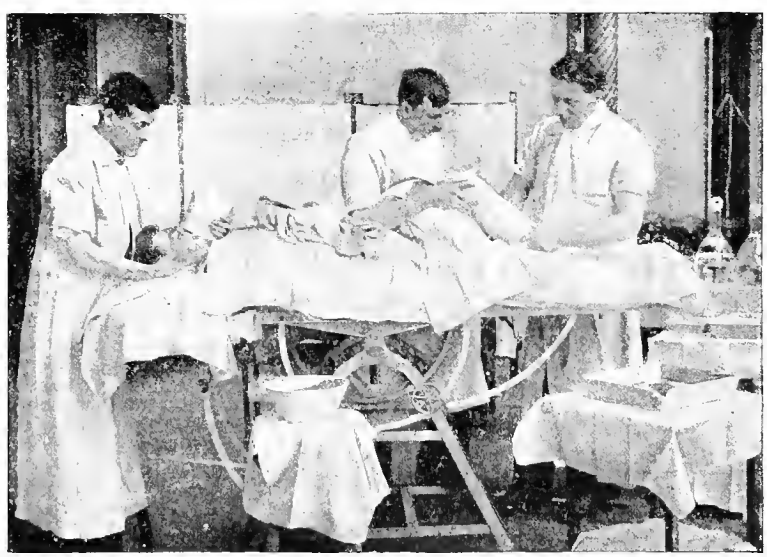


FIG. 708.—Arrangements for Amputation of Leg. (New York Cancer Hospital.) The instruments are in the pan at the right. The ligatures and sutures are on small reels in jars in this pan. Sterilized towels prevent contact with patient's clothing or body. Absorbent pads are in a towel near assistant's right elbow. Basin of sublimate solution for operator's hands is on a stool beside the table. Assistants are in position to hold leg and to sponge and catch bleeding vessels, if necessary. Operator stands at patient's right, beside instrument pan. The jars and flasks in the background are not used in this operation.

staphylococcus epidermis albus. The infective power of this coccus is very slight under ordinary conditions, but the constriction diminished the vitality of the intestine so much that it was unable to withstand the infection of this ordinarily mild bacterium. In a similar way, he found that pieces of potato containing pure cultures of staphylococcus pyogenes aureus produced fatal peritonitis when inserted into the abdominal cavities of rabbits, although they regularly survived the injection of a similar number of these cocci without the potato. The inference is that the mechanical bruising caused by the pieces of potato injured the peritoneum so that it could not withstand the attack of the cocci.

All surgeons have noticed that the portions of a wound which are sewed very tightly, or which are brought together under a strong tension, are more likely to suppurate than those parts which are under less pressure. The undue laceration of a wound, as for instance, scoring of a flap in a Syme's amputation, diminishes the chance of primary healing in the lacerated tissue.

Each particular wound gives its own problems of this nature. Laceration of the tissue in a vascular part, such as the face or scalp, is far less likely to occasion sloughing than it is in a less vascular place, such as the leg or abdominal wall. Patients with a syphilitic taint, or with atheromatous arteries, stand far less laceration than those in a healthy condition.

The Management of Dead Spaces.—There are two methods of dealing with spaces which are made in the tissues. One is, to take buried sutures and in this way draw the tissues together; the other, to allow blood to fill these spaces in the expectation that organization will take place in the clot. The objections to the former method are that the tissues are strangulated, and hence their vitality is greatly impaired, and the large strands of catgut which are used for the buried sutures increase the amount of foreign material in the wound. The other method, the healing under a blood-clot, gives considerable trouble if the clot breaks down and suppuration follows. If, however, the wound is aseptic, some of the most brilliant results in surgery follow.

Schede developed the system and used it extensively for the filling of bony cavities. It has been considerably used since then for the filling of cavities in soft parts. In Phelps's operation for club-foot the gaps between the cut tissues are filled with the blood-clot, and organization should occur there. Halsted has used it with great success. He avoids all laceration or irritation of the tissues, and then allows the cavities to fill with blood. The dressings are left undisturbed for a week or two, sometimes longer. By that time the organization is well advanced in the clot. Acting on this principle he was able to do the remarkable operation of resection of a large aneurism of the first part of the left subclavian artery. He allowed the cavity to fill with blood, in which organization took place, and there was no trouble from sepsis or secondary hemorrhage. So long as it is aseptic, this clot forms a favorable medium in which tissue-formation may take place. It is believed that the tissue-formation takes place in the clot, and not that the clot itself really changes to organized tissue.

The blood-clot method is certainly a good one for those surgeons who are sure of aseptic conditions. But where these conditions do not exist, blood-clots in the wound tend to cause suppuration. Therefore the older surgeons have insisted strenuously on their removal.

This method must be considered one of the refinements of surgery; a very useful one, but one which should be used with caution by those who are not aseptic experts.

Irrigation.—The irrigation of wounds, once so much in use, has now fallen into much disfavor.

It has been practised in the belief that the antiseptic solution used would kill any bacteria which might get into the wound. It has been found that it does not do this, but, on the other hand, it does irritate the tissues and impairs their power of union. In almost all instances it is better to do away with irrigation. The ingress of infection should be prevented, and thus make irrigation unnecessary. Where pus is present irrigation may be used for the mechanical cleansing of the tissues, but not with the idea that it will render the wounds aseptic. I have found that the cultures of the pyogenic bacteria can be made about as easily from wounds which have been irrigated with 1 to 1,000 sublimate solution as from those which have not been irrigated. In the abdominal cavity it sometimes seems wise to irrigate where pus has escaped into the cavity. In such cases a warm six-tenths per cent. sodium chloride solution should be used.

The Drainage of the Wound.—The present tendency is to do away with wound drainage, and we may state that an aseptic wound in a healthy patient need never be drained. The principle of relieving the discharges from a wound and thus diminishing the tension, and carrying away substances which invite suppuration, is certainly a conservative one. Surgeons who are forced to operate under conditions where asepsis is not assured will be wise in using it. It is far better to delay the complete healing for a little time than to risk including septic material in the wound and causing general suppuration. I have known of the fatal termination of a comparatively simple operation, performed by a skilful surgeon, which would have been avoided had drainage been used. I have seen other surgeons of great skill resort to drainage where some occurrences in the operation gave the feeling that asepsis was not complete.

On the other hand, there are many dangers from the use of drainage. One of the greatest of these is that wounds which contain drainage-tubes must be dressed in order to remove the tube, or the discharges which are in or about it. It is far better to leave the dressing undisturbed until healing is complete and the stitches can be removed, than to change it from time to time, and so open new avenues for infection.

Welch has formulated the following objections to the use of the drainage-tubes:

1. They tend to remove bacteria which may get into a wound from the bactericidal influence of the tissues and animal juices.

2. Bacteria may travel by continuous growth or in other ways down the sides of a drainage-tube, and so penetrate into a wound which they otherwise would not enter. We have repeatedly been able to demonstrate this mode of entrance into a wound of the white staphylococcus found so commonly in the epidermis. The danger of leaving any part of a drainage-tube exposed to the air is too evident to require mention.

3. The changing of dressings necessitated by the presence of drainage-tubes increases in proportion to its frequency the chances of accidental infection.

4. The drainage-tube keeps asunder tissues which might otherwise immediately unite.

5. Its presence as a foreign body is an irritant and increases exudation.

6. The withdrawal of tubes left for any considerable time in wounds breaks up forming granulations—a circumstance which both prolongs the process of repair and opens the way for infection. Granulation-tissue is an obstacle to the invasion of pathogenic bacteria from the surface, as has been proven by experiment.

7. After removal of the tube there is left a track prone to suppurate and often slow in healing.

To these Professor Halsted added an eighth:

"That tissues which have been exposed to the drainage-tube are suffering from an insult which more or less impairs their vitality, and hence their ability to destroy or inhibit micro-organisms."

In regard to the question of blood-clot and drainage, we must pay careful attention to two diverse conditions: sepsis and asepsis. Where asepsis exists we can use the blood-clot and can dispense with drainage. Where the condition of the wound or the surroundings of the operation lead us to fear that sepsis is present, it is wise to remove all possible blood from the wound and resort to drainage. As to the material which may be used, perforated rubber or glass tubes are the best. A small opening may sometimes be kept in a wound by inserting a little twist of sterilized or iodoform gauze or rubber tissue.

In doubtful cases a drainage-tube may be put in and removed at the end of forty-eight hours. When this is done primary union need not be prevented. Abscess cavities should be packed with iodoform gauze, allowing the end of the gauze to protrude through the incision. This drains better and irritates the tissues far less than does a piece of hard tubing. Gauze drainage is especially indicated in such abscesses as those incident to appendicitis. These pieces of gauze should not be removed until they are loose in the tissues. The laceration of raw or granulating surfaces is to be avoided.

III. After-Treatment.

The after-treatment should be so conducted as to aid the patient in combating the injuries and to prevent infection. One of the most important features in after-treatment has come with the employment of laxatives. To Mr. Lawson Tait belongs the credit of developing this principle. It is particularly applicable after laparotomies. The former practice was to administer opium and so paralyze the intestines. Mr. Tait pursued the opposite method, and by the use of saline purges endeavored to drain away the serous contents of the abdominal cavity, and so prevent bacterial growth. This treatment is one of the most essential elements in the success of modern abdominal surgery. If the bowels move within two or three days of the operation the laparotomist feels comparatively secure as to the ultimate result. The same principle applies to other surgical operations and to puerperal fever. A purgative diminishes the virulence of infection in almost all cases.

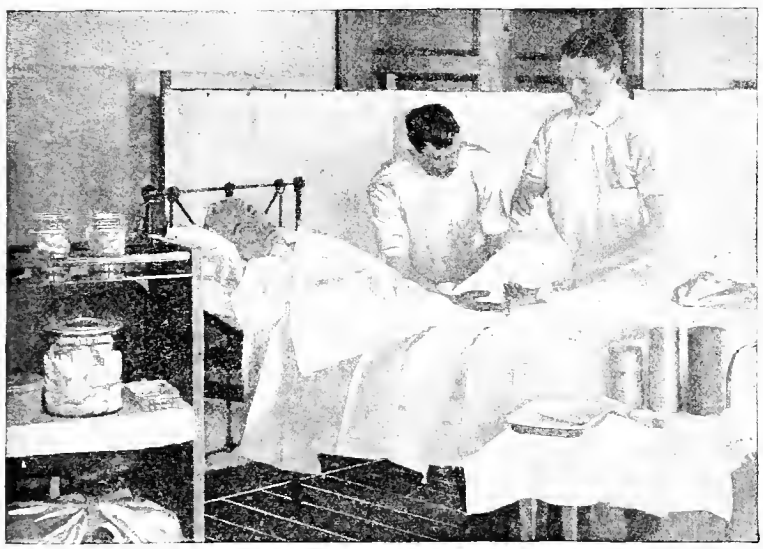

Fig. 709.—First Dressing after Amputation of Leg. (New York Cancer Hospital.) Bed covered with sterilized towels, upon which is a folded towel containing absorbent pads. On stand are placed sterilized dressings in cylinders; scissors and forceps in instrument jam; roll of rubber adhesive plaster. The dressing-case at the head of the bed is not used in this dressing. The surgeon who does the dressing stands at the right of the bed and removes the inner dressing after the outer one has been removed by the assistant.

After-dressing of wounds within a week of the operation should be avoided if practicable. If it is necessary, as for instance, for the removal of a drainage-tube, it should be conducted with all the aseptic precautions which are used in the operation itself. Sterilized towels should be so placed as to prevent any septic contact. Such instruments as are used should be boiled and brought to the surgeon in the dish and solution in which boiling takes place. The surgeon and assistants should cleanse their hands as at the beginning of the operation. The dressing which is to be applied should be sterilized and brought to the bedside either in the sterilizer or in the dressing-cases which have been described above. The outside dressing should be cut away by an assistant. This assistant, and the shears he has used, must then be considered septic until further cleansing has been effected. The outer dressing must then be covered with sterilized damp towels or entirely removed. The inner dressing may be removed by the surgeon. It should on no account be moistened. The moistening of tissues while dressing them renders them far more liable to infection than dry tissues are. Not long ago, in one of the hospitals in this city, a surgeon was greatly perplexed to find that the wounds which regularly looked well at the time of the first dressing afterward broke down and suppurated. He found that the house-surgeon wet the wounds with bichloride solution in order to remove the dressings, and afterward washed them off with the same solution, in the endeavor to make them clean. After stopping this procedure, and having the gauze removed dry, layer by layer, he found that his wounds healed kindly. After the removal of the dressing the surgeon should take out the drainage-tube with a pair of sterilized forceps, and, if all looks well, should immediately apply a new dressing of sterilized gauze. If he considers it necessary to prevent the closing of the drainage opening, he may insert a little piece of sterilized gauze. In this entire procedure nothing but a pair of sterilized forceps should come in contact with the wound. Great care should be taken throughout the entire dressing to avoid injuring the tissues. The patient should be kept from moving as much as is practicable. And in the taking off of the dressing great care should be used to avoid pulling or stretching the parts. If slight suppuration occurs it is usually best treated by absorbent sterilized dressings frequently applied. If these absorb and dry the discharge, healing will quickly follow. If suppuration is too extensive for this, thorough drainage should be obtained by reopening as much of the incision as is necessary, and packing the wound with iodoform gauze.

Peroxide of hydrogen is useful in cleansing such wounds. Their undue irrigation and irritation in the dressing is to be avoided. Where suppuration involves such structures as the knee-joint, the continuous irrigation of water or mild antiseptic solution may be used.

The after-treatment in such operations as excision of the tongue or superior maxilla, resection of intestine, opening of the bladder, etc., varies with each operation. They involve no new principles, and there is not space here to consider them in detail.

Where large granulating surfaces or cavities exist, balsam of Peru is a useful stimulant. It may be injected, or strips of gauze may be saturated with it, and then inserted into the wound. In the management of such wounds care must be used lest there be burrowing and pocketing about its margin. Where there is such burrowing free incision should be made at once.

Throughout all of these details the technique is made with the effort to irritate the tissues as little as is possible, and to keep out infection. The operator may expect success according as he is able to fulfil these two requirements. As a practical illustration of the working of these methods I will give the history of a case of amputation of a leg, as done at the New York Cancer Hospital:

The patient was a man of twenty-three, who had suffered in boyhood from tubercular ulcers in various parts of his body. For four years a sarcoma had been grow-

ing in the calf of the leg; at the time of operation it was as large as a cocoa-nut. He was emaciated and in poor condition. Before the operation his oral temperature was frequently 100° or 101° F., and while he was taking the ether his pulse went up to 150. It was manifestly important to get the leg off with the least possible shock and without sepsis. Much shock or much sepsis would, either one, have been fatal to the patient. The arrangement of the patient, assistants, and instruments, is shown in Fig. 708. The operator stood beside the instrument-case at the patient's right. The instruments were transferred from the boiler directly to the instrument-tray, without touching anything. Some retractors, etc., were in another tray within reach of the assistants. Gauze pads were used instead of sponges; they were sterilized in steam, and are seen pictured in the towel which held them. The catgut is in the little holders in the instrument-tray. The silk-worm-gut was boiled with the instruments, several strands were threaded before the boiling. As the operation was short, and not many instruments were needed, the operator took his instruments and the catgut directly from the tray. The dressings were sterilized in cylinders, and were not removed from them until they were applied.

In glancing at these arrangements it will be seen that there was hardly any opportunity for septic contact. Drainage was not necessary in this case, but as the patient's condition was so bad, two small tubes were put in as a safeguard. Carden's amputation was done, making the flaps rather longer than those he describes.

On the afternoon following the operation his temperature went to 101° F., but as it had frequently done this before the operation, little importance was attached to it. The next morning it was normal, and it remained so steadily. On the second day the dressing was taken down and the tubes removed; the arrangements for this are indicated in Fig. 709. The wound was aseptic. On the ninth day the dressing was again taken off and the stitches removed. Healing was then complete by first intention, without a drop of pus at any part of the wound.

This case is cited to show what results may confidently be expected, even in debilitated patients, when stringent aseptic precautions are employed.

Charles N. Dowd.

ZINC, POISONING BY. The most important salts of zinc, from a medico-legal point of view, are the sulphate and chloride.

Zinc sulphate, or *white vitriol* ($ZnSO_4$, $7H_2O$), is a colorless salt, crystallizing in small four-sided prisms, which slowly effloresce in dry air. It is soluble in about two times its weight of water at the ordinary temperature, and in less than its own weight of boiling water; insoluble in alcohol, ether, and chloroform. Its taste is astringent and metallic; its reaction, acid.

Zinc chloride ($ZnCl_2$), commonly called *butter of zinc*, is a soft, white, very deliquescent, readily fusible solid, freely soluble in water and in alcohol. Its taste, in the solid state or in concentrated solution, is acrid and corrosive; in dilute solution, astringent and metallic. Its reaction is acid. When brought into contact with raw surfaces or mucous membranes it acts as a corrosive. It has considerable antiseptic power also, and, in aqueous solution, is frequently used as an antiseptic, deodorizer, and disinfectant. The liquid known under the name of "Sir William Burnett's disinfecting fluid" is such a solution, containing over 200 grains of the salt in each fluid-ounce.

Cases of poisoning by these salts have been of rare occurrence, and usually the result of accident. Zinc sulphate resembles magnesic sulphate (Epsom salts) very closely in its appearance, and has frequently been taken by mistake for the latter, while Burnett's fluid, which has been the cause of most of the reported cases of poisoning by zinc chloride, has frequently been mistaken for water or other harmless liquid.

Symptoms.—Zinc sulphate acts as an irritant poison, but only when a large quantity has been taken. The symptoms are almost entirely local. The most prominent are: an astringent and metallic taste, burning pain in the œsophagus, stomach, and bowels, nausea, vomiting, purging, dyspnœa, small and frequent pulse, and cold extremities. The intellect usually remains clear.

The symptoms usually make their appearance almost immediately after swallowing the poison; but, in rare cases, have been more or less delayed.

Wormley quotes a case in which vomiting was delayed for fifteen minutes, and there was no purging for ten hours. In this case a solution containing 46.5 grammes (℥ jss.) of the salt was swallowed. In a case communicated by Lutier active symptoms appeared first after the lapse of fifteen hours.

The symptoms produced by zinc chloride are similar in character to those just described. This salt has, however, a violent corrosive action, which is wanting in the sulphate. The local symptoms are therefore usually more severe than they are in cases of poisoning by the sulphate, and are more frequently followed by symptoms of profound collapse and death. In non-fatal cases recovery may not be complete until after the lapse of several days, or even weeks.

The investigations of C. Ph. Falck, Blake, Letheby, and Harnack show that the salts of zinc paralyze the striated muscles and cause death by their action on the heart and muscles of respiration, without influencing, to any great extent, the central nervous system. F. A. Falck, who experimented with rabbits, found that the

temperature of the body is reduced 7° to 13° C. in cases of acute zinc poisoning.

Fatal Quantity.—Fatal Period.—The quantity of any of the preparations of zinc required to endanger life is not exactly known. The sulphate is not a powerful irritant. In large doses it acts as a prompt emetic, and is frequently rejected by the stomach without producing any other serious symptoms. Quantities varying from 4.3 to 124 grammes (67 grains to ʒ iv.) have been taken without fatal result. Death has occurred in five hours (a child), thirteen and a half hours (adult, 5.8 grammes), thirty-six hours (7.6 grammes), three days (adult, quantity unknown), and five days (adult, 15.5 grammes). The chloride is much more dangerous than the sulphate. Most of the reported cases of poisoning by this salt have been caused by Burnett's solution, and the quantity taken has usually been known only approximately. Recovery has followed the administration of quantities of this solution varying from half a wineglassful to three fluid-ounces, the quantity of salt varying, so far as known, from 0.8 to 26 grammes (12 to 400 grains). Six and one-half grammes (100 grains) has caused death. Death usually takes place within twenty-four hours. The shortest fatal periods are two hours (Taylor), four hours (Allanson), seven and a half hours (Cousins), ten hours (Letheby). Occasionally the patient has recovered from the primary effects, only to succumb to the secondary effects after the lapse of several weeks. In such cases death usually results from starvation, following upon stricture of the œsophagus, pylorus, or intestines.

Post-mortem Appearances.—When the sulphate has been taken, the lesions are substantially similar in character to those observed in cases of poisoning by other pure irritants. A slight ulceration, near the pyloric end of the stomach, has been noted in a single case. Rarely, there may be contraction of the stomach or intestines.

The chloride of zinc resembles in its action the mineral acids and caustic alkalies. In cases of poisoning by this salt the mucous membranes of the mouth, throat, œsophagus, stomach, and intestines are usually more or less disorganized. In a few cases, however, there has been an absence of corrosion even in the mouth. Perforation of the stomach, and stricture of the œsophagus, pylorus, and intestines may be met with, especially in cases which are not rapidly fatal. Congestion of the brain and its membranes, and of the lungs and kidneys, are usual sequels of acute poisoning.

Treatment.—Vomiting should be encouraged if necessary. Sodic carbonate precipitates and zinc carbonate from solutions of soluble zinc salts may therefore be employed as a temporary chemical antidote. In other respects treatment must be symptomatic.

Other Compounds of Zinc.—The remaining soluble salts of zinc are, substantially, duplicates, in their effects, of the sulphate or chloride.

Zinc oxide and *zinc carbonate* are white amorphous solids, insoluble in water, but soluble in dilute acids, the carbonate dissolving with effervescence. Either of these compounds, if taken internally in considerable quantity, may dissolve in the fluids of the stomach and intestines and give rise to acute or subacute poisoning, with the usual symptoms of irritant poisoning.

Chronic zinc poisoning has been ascribed to the long-continued inhalation of the vapors of zinc oxide. This form of poisoning has been observed in workers in zinc, brass, and galvanized iron, and is characterized by headache, chilliness, pains in the extremities, a strong metallic taste, nausea, vomiting, diarrhœa, and colic. It is to be borne in mind in this connection that commercial zinc usually contains lead, and frequently arsenic, and that the above symptoms may be those of poisoning by one or the other of these metals, and not by zinc oxide.

The use of galvanized iron pipes for conveying water, and of galvanized iron utensils for the preparation and storage of food, appears to be attended with some danger. Water that has passed through galvanized iron pipes almost always contains zinc compounds, either in solution or in suspension. There is some difference of opinion as to the effect of such water on health, but it is generally believed that the danger of poisoning from the zinc in solution in the water is very slight. When the water has stood in contact with the pipe for several hours it frequently holds in suspension a considerable quantity of insoluble zinc compounds. It seems probable that the use of such water would be attended with danger. As a precautionary measure, therefore, the water that has stood in contact with a galvanized iron pipe for several hours should be allowed to run to waste, or should be filtered before use.

Certain liquids used in cooking, especially such as contain vegetable acids, may dissolve a sufficient quantity of zinc from galvanized iron utensils to produce symptoms of poisoning. Wormley reports a case of zinc-poisoning caused by the use of apple butter prepared with cider which had been concentrated in a galvanized iron pan. The concentrated cider was found to contain 1.14 grain zinc oxide to each fluid-ounce.

Absorption and Elimination.—When compounds of zinc are taken internally the metal is absorbed, presumably in the form of albuminate, and may be detected after death in the blood and in all the tissues of the body. Matzkewitsch administered the acetate of zinc to dogs by subcutaneous injection, and found, as the result of five experiments, that the greater proportion of the zinc thus introduced was localized in the muscles and bones. The skin, brain, liver, heart, lungs, kidneys, bladder, stomach, and intestines contained zinc, but in relatively small quantities. Zinc is eliminated with the urine, bile, and milk (Falck, Harnack). According to Michaelis the metal is first detected in the excretions on the fourth or fifth day after the administration of its compounds. The time required for complete elimination is unknown. According to Popoff it can be detected in the urine for months after removal from its influence.

The study of the localization and elimination of zinc is attended with peculiar difficulties, inasmuch as the human system frequently contains small quantities of the metal even when its compounds have not been purposely administered. Raoult and Breton isolated 7 milligr. of zinc from 700 grammes of human liver in one case; 12 milligr. from 400 grammes of liver in a second case. In four other cases they extracted 10, 30, 34, and 76 milligr., respectively, from 1,000 grammes of liver. Lechartier and Bellamy obtained similar results. In one case 1,780 grammes of liver contained 20 milligr. of zinc oxide. The same authors extracted 30 milligr. of zinc oxide from 913 grammes of muscle from the ox, and 20 milligr. from 1,152 grammes hard-boiled egg. They also detected traces of zinc in corn, maize, barley, and white beans.

The frequent presence of small quantities of zinc in the organs of the body may be explained in some cases by the use of water which has been conveyed through galvanized iron pipes, or by the use of food which has absorbed zinc from galvanized iron utensils; in other cases, by the medicinal administration of preparations of zinc before death, or the introduction of embalming fluids containing salts of zinc, after death.

In consideration of the foregoing facts it is obvious that the detection of zinc in the tissues after death cannot, when unsupported by other evidence, be accepted as proof that death was caused by zinc-poisoning.

William B. Hills.

ADDENDUM.

PLASMODIA MALARIÆ. Although one of the criteria which are generally demanded to establish the parasitic nature of a disease is yet wanting in malaria, still the evidence is quite convincing that the disease is caused by a specific micro-organism; or, more probably, by several different organisms which are nearly alike, but differ from each other in each type of the disease; one kind of parasite causing tertian fever, another but similar organism causing quartan fever, etc. The break in the chain of evidence is the fact that the parasites have not yet been cultivated upon artificial media. Still the observations of a great many trustworthy observers, agreeing as they do in everything except a few matters of minor detail, leave little room for doubt. The parasites are classed as protozoa, and are called the plasmodia malariæ. They are always found, according to all observers, in the blood of persons suffering from malaria, and are not found in the blood of any other persons. The only matter about which there is still a difference of opinion is whether there is only one micro-organism which causes all the different forms of malaria, or whether there is a different micro-organism for each of the forms of malaria which present diverse clinical peculiarities. Barbacci,[1] from whose admirable review I have taken most of the data for the present brief article, has carefully sifted the literature upon the subject of the malarial parasites. He finds that the authorities may be divided into two schools: Laveran and his followers on the one hand, and the Italian school on the other. American observers seem to favor the views of the Italian school. Laveran holds that a single kind of parasite is the constant cause of malaria, and that the polymorphic varieties of this parasite have no close connection with the different clinical phenomena of the various forms of malaria. The Italian school, on the contrary, contends that there are different kinds of malaria-organisms, which bear a close relation to one another, but which are not identical; and that each different clinical form of the infection is dependent upon the cycle of development of its peculiar parasite. According to Laveran the fully developed organism is represented by moving filaments which are developed within small cystic bodies, the so-called pigmented bodies, and finally become detached from these, and move about in the blood plasma; whereas the Italian school regards the amœba, or plasmodium of Machiafava and Celli, as the fundamental form of the organism. This is a more or less round mass of protoplasm containing no pigment granules, and endowed with amœboid movement. Finally, Laveran maintains that those organisms which are not found floating around free in the blood are merely in contact with the red blood-corpuscles, or are at most simply attached to these, but not in them. The Italian school, on the contrary, maintains that the parasite in these cases is in the red blood-corpuscles; that it derives its nutrition from the hæmoglobin of the latter, and goes through many or all of its phases of development, even to reproduction, inside the red blood-corpuscles.

Laveran clearly deserves the credit of having first established the parasitic nature of the cause of malaria, and the fundamental facts which he has established no longer meet with serious opposition. The matters in dispute, as stated above, are mainly questions of interpretation.

Before going on to describe the micro-organisms, a few words as to the methods of preparing the blood for examination may not be amiss.

The blood may be examined fresh without any special preparation, or it may be examined by staining it with different dyes, either with or without previous fixation on the glass by means of various fixing agents. If no special or prolonged study is needed, it is only necessary to take a very small drop, half the size of a pin-head, from the spleen, or end of the finger, or from the lobe of the ear. For puncturing the finger or lobe of the ear it is better to use a very fine lancet rather than a needle. After the puncture is made a cover-glass, which must be thoroughly clean, is applied to the drop of blood which appears, and is then simply placed on the slide and examined. Preparations of this kind can be used for examination for a longer time if the edges of the cover-glass are sealed around to the slide with paraffin to prevent evaporation.

It is usual to make colored preparations, and for this purpose the aniline dyes are best, especially a concentrated alcoholic or aqueous solution of methylene blue. The cover-glasses with the blood spread over them are allowed to dry, passed over a flame in order to fix the blood, and then placed in the alcoholic solution for half a minute, or in the aqueous solution for one or two hours. After staining, the dye is washed off with water and the specimen may be examined at once; or it may be allowed to dry and then mounted in balsam; or better still, in a concentrated solution of gum arabic. There are a great many modifications and improvements on this method, such as the use of special fixing and hardening reagents, and the use of contrast stains, many of which will suggest themselves. An account of all the various methods will be found in Barbacci's article above referred to.

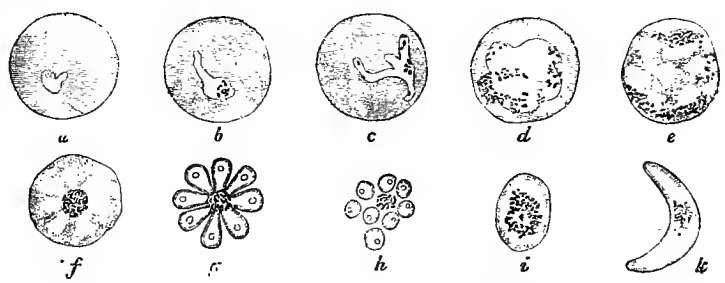

FIG. 710.—Plasmodium Malariæ of a Quartan Fever in Different Stages of Development (according to Golgi). *a*, Red blood-corpuscles containing a small non-pigmented plasmodium; *b*, *c*, *d*, *e*, plasmodia varying in size, inside red blood-corpuscles and containing pigment granules; *f*, plasmodium at the beginning of pigmentation with pigment in the centre; *g*, a segmented plasmodium, *h*, *a*, plasmodium segmented into little spheres, *i*, *k*, two free plasmodia of different shapes. (Ziegler: Lehrbuch d. All. Path. Anat., 7te Auflage, p. 622, Fig. 384, Jena, 1892.)

Laveran[2] in his recent book clearly defines his interpretation of the different pictures met with in preparations of malarial blood. According to Laveran the malarial parasite exhibits a variety of different forms, all of which can be brought together under one of four fundamental types:

1. *Spherical Bodies.*—These are spheroidal bodies with amœboid movement, varying in size from 1 μ to twice the size of a red blood-corpuscle (Fig. 710 *h*, *i*). The smaller forms are devoid of pigment, but as they increase in size they take up pigment granules, and these granules are then seen to have a lively oscillatory movement. The movement, according to Laveran, is probably imparted to the granules by the amœboid changes of the plasmodium. The spherical bodies are either free in the plasma, or are in contact with the red blood-corpuscles from which they derive their nutrition. It is still a disputed point whether they possess nuclei and reproduce by segmentation. They are the commonest forms met with in malaria.

2. *Bodies with Flagella.*—These are spherical bodies free in the blood plasma, with long moving filaments (Figs. 711, *f*, and 712, *g*) attached. At a certain stage these flagella separate from the spherical bodies and swim around free in among the blood-corpuscles. Laveran says that at this stage it is perfectly evident these flagella have an independent existence, and that they constitute the most characteristic form which the malarial parasite assumes.

3. *Crescents.*—These are semilunar bodies or crescents with more or less pointed ends (Figs. 710, *k*, and 712, *e*, *f*), consisting of a colorless substance and having pigment granules about the centre. They are double-contoured, and have usually a long diameter greater than that of a red blood-corpuscle. They are found lying free in the blood plasma, or when they are attached to the red blood-corpuscles the attachment is so slight that it is easily broken by a slight jarring of the preparation. They are without motion and devoid of flagella. The pigment contained in them is also motionless. By observing them for some time under the microscope they are seen gradually to assume first an oval, and then a spheroidal, shape. They are oftenest seen in patients with malarial relapse, or with malarial cachexia.

4. *Rosettes.*—These are elements floating around free in the blood (Fig. 710, *g*), pigmented in the central part, and regularly divided into a varying number of round or oval bodies.

All of these four forms are to be regarded, according to Laveran, as merely successive phases in the development of one and the same organism, and not as separate and distinct organisms, in spite of the great differences in shape. The small, hyaline, unpigmented bodies on the red corpuscles are probably the embryo stage of the parasite. From this stage the organism gradually increases in size to that of a red blood-corpuscle or more, and also gradually takes up pigment granules. These bodies are possessed of amœboid movement, live free in the plasma, attach themselves to the red blood-corpuscles, deriving their nutrition and also the pigment granules from these. The flagella develop inside of these bodies, and at a certain stage become liberated. Laveran, moreover, holds that there is no relation between the different forms of the organism and the different clinical types of malaria. He claims that the most that can be said is that certain of the forms are oftenest seen in certain types of malaria, as, for example, the crescents in relapsing fever and malarial cachexia.

The attitude of the Italian school has been well formulated by Golgi. Golgi claims that the plasmodia develop inside the red corpuscles, and the first stage is the appearance of a small, colorless, amœboid body in the red

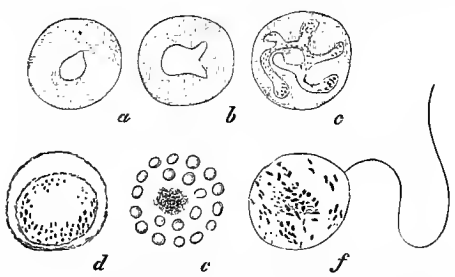

FIG. 711.—Plasmodium Malariæ of a Tertian Fever in Different Stages of Development (according to Golgi). *a*, First stage; *b*, *c*, plasmodia increased in size with amœboid processes; *d*, plasmodium before sporulation, blood-corpuscle decolorized; *e*, sporulation; *f*, free parasite with flagellum. (Ziegler: Lehrbuch der All. Path. Anat., 7te Auflage, p. 623, Fig. 685.)

corpuscles (Figs. 710, *a*, 711, *a*, 712, *a*, *b*). In this stage the organisms of different types of malaria are indistinguishable. The character of the further development depends upon whether the organism is that of quartan, tertian, or quotidian fever.

In quartan fever further development consists in a gradual increase in the size of the plasmodium (Fig. 711, *b*, *c*, *d*, *e*), which occupies more and more of the red blood-corpuscle; at the same time pigment granules appear inside the parasite, which are made up of the coloring matter of the blood-corpuscles. After the plasmodium has attained a certain size the pigment granules accumulate toward the centre, and at the same time a radiating segmentation takes place, producing a rosette-like figure

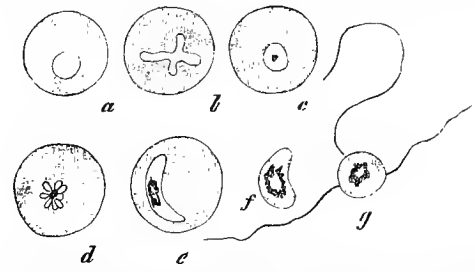

FIG. 712.—Plasmodium Malariæ of a Quotidian Fever in Different Stages of Development (according to Celli and Sanfelice). *a*, First stage in the development; *b*, plasmodium with amœboid processes; *c*, plasmodium which has become round and contains pigment, before segmentation; *d*, sporulation; *e*, intra-globular crescent; *f*, *g*, free forms. (Ibid., p. 624.)

(Fig. 710, *f*, *g*), consisting of a pigmented centre surrounded by from six to twelve colorless, radiating, pear-shaped bodies, with the clubbed extremities toward the periphery. Subsequently the pear-shaped bodies are liberated and assume a spherical shape. These phases are completed in three days in the quartan type of fever, and the appearance of fever takes place simultaneously with the segmentation of the plasmodium. The red corpuscles which contain the parasites are destroyed, and the liberated plasmodia force their way into the bodies of other red corpuscles and begin development anew. The pigment granules are some of them set free, while others are taken up by the cells of various organs, notably the spleen and liver.

In tertian fever the development of the plasmodium takes place in two days. The amœbæ in this case show a much more active amœboid movement, and decolorize the red blood-corpuscles much more quickly than in the quartan form. In the tertian fever the red corpuscles become decolorized on the first day of the fever, while the plasmodia are still small. The protoplasm of the tertian plasmodium is more delicate and less sharply outlined, and the pigment granules are finer than in the quartan type (Fig. 711, *a*, *b*, *c*). The number of segments into which the plasmodium of tertian fever breaks up is about double that of the quartan fever (Fig. 711, *e*). Machiafava and Celli regard this segmentation as a sporulation, and have noticed it taking place before the red corpuscle is destroyed, and have seen red corpuscles containing from five to ten spores. In tertian, moreover, the red corpuscles generally retain their shape till they are destroyed, whereas in quartan malaria the red blood-corpuscles become wrinkled.

In quotidian fever and pernicious malaria, according to Celli and Sanfelice, the parasite consists of a small body with very active amœboid motion inside the red blood-cell. Shortly before an attack of fever the parasite becomes pigmented and globular, and then segments into spores.

Besides all these forms the Italian observers substantiate Laveran's observations of intra-corpuscular, and free, round, oval, or half-moon-shaped bodies as well as round bodies with filaments (Figs. 710, *i*, *k*, and 711, *f*, and 712, *f*, *g*).

The semilunar forms and the filamented forms are regarded as sterile; they are not capable of reproduction, and sooner or later are destroyed. Some authors regard the crescentic bodies as the cause of the typical more or less continued fevers of summer and autumn, the æstivo-autumnal fevers, which are apt to be pernicious. It is also claimed by some that they are not seen inside the blood-corpuscles, and neither inside nor outside in quartan or tertian, but only in æstivo-autumnal fever.

The plasmodia are taken up by the leucocytes at any and all stages. Leucocytes can be consequently observed with whole plasmodia in them, or with fragments of these, or simply with pigment granules.

Dr. W. S. Thayer, of the Johns Hopkins Hospital, who has had a great deal of experience in examining the blood of malarial patients, tells me that he has never found organisms such as are represented by *i*, *k*, Fig. 710, in quartan fever, but that they are only met with in quotidian.

Machiafava and Bignami [3] sum up the facts thus far established in regard to the etiology of malaria about as follows:

1. Malaria is a parasitic disease caused by a hæmatozoön belonging to the protozoa, and not to the schizomycetes.

2. The malarial hæmatozoa are amœbæ, which develop inside the red blood-corpuscles, changing the hæmoglobin of the latter into melanin, or causing a rapid toxic necrosis of these; this is the source of malarial anæmia.

3. The malarial amœbæ complete their cycle of life in the bodies of the red blood-corpuscles. They begin as unpigmented but actively moving bodies, and these develop, finally becoming pigmented, and then multiply by segmentation into spores. The spores become amœbæ and enter into the red corpuscles, thus completing the cycle.

4. This cycle corresponds with the periodic recurrence of the attacks; the sporulation (segmentation) is coincident with the beginning of every attack of fever.

5. Everything points to the probability that during the course of their development and growth the amœbæ produce a pyrogenic poison, though this has not yet been demonstrated. The fundamental changes in the red blood-corpuscles, and the changes in the parenchyma of some of the organs, are almost certainly due to the action of this poison.

6. Each type of fever has a parasite with certain biological and morphological peculiarities, so that the necessary conclusion is that there are several varieties or species of amœbæ in malaria. The difference in the biological and pathogenic peculiarities of the parasites is in each case an index of the type of the fever. Differences can now be made out between the amœbæ of quartan fever, the amœbæ of tertian fever, the amœbæ of the æstivo-autumnal fever, and the amœbæ of quotidian fever. The pernicious fevers are only caused by the last two varieties of amœba, and the presence of these amœbæ always indicates a pernicious type of fever. So that benign and malignant fevers may be differentiated by examination of the blood alone.

7. The malarial amœbæ cause changes not only in the blood, but also in the blood-vessels of all the organs, and in the parenchyma of many of these (spleen, kidney, bone-marrow). The changes in some of the organs are temporary and explain the symptoms which accompany the acute infection. In other organs (spleen, liver, bone-marrow) the changes are permanent, and account for the chronic anæmia and the symptoms of chronic infection and malarial cachexia.

on hydrops articulorum intermittens, 484
Basedow's disease, see *Goître, exophthalmic.*
Basilar arteries, aneurism of the, paralysis of the external ocular muscles in, 304
Bastard fertilization, 407
Baths, cold, in typhoid fever, 915
Battle, care of the wounded in, 649
Beberine, 481
Beer, production of, 1036
Belladonna poisoning, eye symptoms in, 297
Benzanilide, 89*, 843
Benzene, the basis of the aromatic series, 841
Benzoazurin, 430
Benzoic acid, synthetic formation of, 841
Benzol, the basis of the aromatic series, 841
Benzo-naphthol, 843
Benzopurpurin, 430
Benzosol, 388, 843
Bertrich, 89*
Beta-naphthol benzoate, 90*
Betol, 90*, 843
Bex, 90* (Fig.)
Bile, action of mercury upon the secretion of, 623
Bile-ducts, operations upon the, 344
Bilin, 91*
Biliousness, mercury in, 626, 629
Births, registration of, 969, 974
Biskra, 91*
Bismarck brown, 430
Bismuth, subgallate of, 212
Blackader, A. D., on artificial feeding of infants, 49
Blackpool, 91*
Bladder, exploration of the, by the cystoscope, 372 (Fig.)
exstrophy of the, 370
inflammation of the, 370
injuries of the, 371
new growths of the, 371

Bladder, recent advances in the surgery of the, 370
stone in the, operations for, 371
tuberculosis of the, 372
Blepharitis, diagnostic significance of, 293
Blepharospasm, causes of, 294
Blind headache, 303
Blindness, temporary, causes of, 302
Blodgett, Albert N., on intra-vascular and subcutaneous infusions of blood and of saline solutions, 547
on rabies, 759
Blood, analysis of gases in the, 370
changes in the, in gout, 384
colorless corpuscles in the, 635
effect of mercury upon the, 622
examination of, for bacteria, 80
histological examination of, 435, 634 (Fig.)
intra-vascular and subcutaneous infusion of, 547
Blood-corpuscles, red, measurements of, 94
Blood-serum therapy, 54
Blood-stains, 91*
Blood-vessels, changes in the, in acromegaly, 6
of the lungs, 575
Bocklet, 96*
Boils, mercury for, 630
Bolton, Meade, on artificial immunity, 51, 492
on bacillus pyogenes soli, 77
on plasmodium malariæ, 1058
on symptomatic anthrax, 44
on the bacillus of tetanus, 862
Bone, operations upon, results of, in old age, 700
plates, decalcified, in intestinal anastomosis, 538 (Fig.)
temporal, mastoid process of the, 598 (Fig.)
transplantation of, 96*
tuberculosis of, treatment of, 910
Bormio, 97*
Boulogne-sur-Mer, 97*
Bourbonne-les-Bains, 97*
Bourboule, la, 98*
Bow-legs, 99* (Fig.)
Brain, alinjection of the, 115
and body, relative weights of the, 111
arterial injection of preservative fluid, 114
arteries of the, 138
arteries of the, location of, 114
cerebellar cortex, 101
cerebellar entocinerea, 101
ciliary body of the cerebellum, 102
conarium, 102
corpus denticulatum, s. fimbriatum, s. ciliare, s. lenticulatum, of the cerebellum, 102
dentatum of the cerebellum, 101
determining the volume of the, 117
dissection of the, 118
diseases of the, eye symptoms in, 301, 302, 304
dry preparations of the, 113
embolus of the cerebellum, 102
endymal cilia, 101
entocœlian injection, 113
epiphysis, 102
fastigatum or fastigial nucleus of the cerebellum, 102
fifth ventricle, 103
fissures, 107, 687
Brain, fornix, 103
globulus of the cerebellum, 102
gross or macroscopic anatomy of the, 99* (Fig.)
hippocamp, 103
homologies of the central and cruciate fissures, 109
importance of early recognition of the form and connections of the encephalic cavities, 112
incallosal, 104
indusium, 104
intra-parietal sulcus, 687
labelling specimens of the, 117
lymphatics of the, 141
medio-commissure of the, 102
methods of removing, preserving, dissecting, and drawing the, 111* (Fig.)
need of the study of the, 110
neuraxis or neuron, choice of term, 100
nuclei of the cerebellum, 102
nucleus emboliformis of the, 102
paraphysis, 103
pineal body, 102
præcentral sulcus, 687
preservative liquids for the, 113
pseudocœle, 103
relations of the thalamus to the paracœle, 106
rhinocephalic segment, question of the existence of a, 101
rhinocœle, 103
roof-nuclei of the cerebellum, 101
sinuses of the, 141 (Fig.)
tectal nuclei of the cerebellum, 101
tumors of the, 121*
tumors of the, localization of, 136
tumors of the, operable, 138
tumors of the, meningitis from, 617
tumors of the, tables of cases operated upon, 122
types of cortical cells, 684 (Fig.)
veins of the, 140 (Fig.)
ventriculus septi pellucidi, 103
vessels of the, 138* (Fig.)
weighing the fresh, 117
weight of the, 111
Brannan, John Winters, on typhus fever, 919
Brassard of the red cross, the distinctive badge of privates of the hospital corps of the United States Army, 325
Breast, results of amputation of, in old age, 700
Breath screen for microscopical work, 443 (Fig.)
Brewer, George Emerson, on genito-urinary surgery, 370
Brides-les-Bains, 141*
Bridge, Norman, on diarrhœa, 212
on gonorrhœal rheumatism, 381
on headache, 389
Bright's diseases of the kidney, Delafield's classification of, 142*
Bromoform, 146*
synthetic formation of, 840
Bromol, 146*, 843
Bronchus, divisions of the, 572
Broom, alkaloid of, 814
Browning, William, on vessels of the brain, 138
Bryant, Joseph D., on movable bodies in joints, 562
on wounds of the intestines, 541
Bubo, so-called tertiary, 856
Burettes for gas analysis, 356 (Fig.)
Bussang, 146*
Button-anastomosis of the intestines, 348 (Fig.), 539
Buxton, 147*
Byers, J. Wellington, on the general principles of prophylaxis, 751
Byford, Henry T., on carcinoma and fibroid tumors of the uterus, 922

Cactus grandiflorus, 147*
Cæcum and appendix, diseases of, 147*
Caffeine, 149*
Calculus, biliary, operations for, 343
vesical, operations for, 371
Calliandra Houstoni, 709
Calomel, cholagogue action of, 623
diuretic action of, 237
Cambo, 150*
Camphor, naphthol, 660*
Camphoric acid, 150*
Canada, climate of, 151*
Canary Islands, 155*
Cancer, curative treatment of, by erysipelas, 784* (Fig.)
growths analogous to, in animals and plants, 791
microscopical diagnosis of, 637
of the uterus, 922*
parasitic nature of, 791
pyoctanin in, 756
sporozoa in, 637
Cannabine, 156
Cannabinon, 156
Cannabis indica, 155*
Canstatt, 156*
Cantharidinate of potassium, 156*
Carbolic acid as an antiseptic, 755
synthetic formation of, 841
Carbon bisulphide, poisoning by, papillitis in, 300
dioxide, determination of, in the atmosphere, 365 (Fig.)
monoxide, determination of, in the air of rooms, 368 (Fig.)
tetrachloride, formula of, 840
Carbonic-acid gas, compressed, for the freezing microtome, 440 (Fig.)
Carbonic oxide, poisoning by, paralysis of the external ocular muscles in, 304
Carica papaya, 712
Carmalum, 428
Carmine for tissue staining, 428
Cars, railroad, sanitary inspection of, 778
Cartilages, semi-lunar, displacement of the, 562
Cassia oil as a mounting medium, 438
Cataphoresis, 266
Cataract, 157*
diagnostic significance of, 298
Catgut mats in intestinal anastomosis, 538
Catheterization for retention of urine, 374
Causation of disease, the science of, 21
Cells, cerebral, trophic changes consequent upon the processes of waste and repair in the, 505
cortical, types of, 684 (Fig.)
Purkinje, 434 (Fig.), 684 (Fig.)
sexual, Watase's method for differentiating, 435

Cellular therapy as exemplified by the action of mercury, 622
Census, the, 966
Centre, thermic, 308
Centrifugal machine for precipitating fluids, 78 (Fig.), 636 (Fig.)
Centrosomes, 402 (Fig.)
Cephalalgia, 389*
Cerebellum, anatomy of the, 101
minute anatomy of, in mammalia, 683
tumors of the, 138
Cerebral cells, trophic changes consequent upon the processes of waste and repair in the, 505
Cerebral cortex, power of inhibition possessed by the, 505
Cerebro-spinal meningitis, choroiditis in, 298
Cerebrum, fissures of the, 684
Cereus, night-blooming, 147
Chalazion, tuberculous, 293
Chancre, excision of, powerless to prevent general syphilis, 847
Channel Islands, 159*
